## CLXXIX. RESEARCHES ON THE PHOSPHATASES.

### III. ON THE MECHANISM OF THE INACTIVATING ACTION OF SODIUM OXALATE AND OF PHOS- PHATES ON THE "ALKALINE" PHOSPHATASES OF ANIMAL TISSUE.

By SERAFINO BELFANTI, ANGELO CONTARDI  
AND ALBERTO ERCOLI.

*From the Istituto Sieroterapico Milanese—Regio Istituto Superiore,  
Agrario, Milan.*

*(Received March 7th, 1935.)*

In our first report [Belfanti *et al.*, 1935, 1] we dealt with the fact that, in many extracts of animal organs, the existence may be noted of a second "optimum" of phosphatase activity in an acid medium besides that optimum (which has been known for a long time) which exists in an alkaline medium<sup>1</sup>.

Without prejudging the question as to whether the phenomenon is due to differentiation between the active groups of the enzymes themselves or to a diversity of colloidal carriers, we adopted, for the sake of greater clearness, the terms acid<sup>2</sup> phosphatases and alkaline phosphatases and we studied the different effects exercised by several inhibitory agents on these two forms of phospho-esterase activity.

In the present work, we have devoted our attention exclusively to the study of the effect of sodium oxalate on the alkaline phosphatases in order to decide whether or not the alkaline phosphatases of various origins studied up to the present may be considered as identical, and to find an explanation for several divergencies observed between the experimental data obtained by us and by Munemura [1933].

#### THE ACTION OF SODIUM OXALATE ON THE ACTIVITY OF THE ALKALINE PHOSPHATASES OF LIVER AND BONE EXTRACTS.

The methods employed were the same as those previously described [Belfanti *et al.*, 1935, 1, 2].

The extract of liver was prepared as previously described. The extract of bone was obtained from the tibiae and femora of an adult rabbit; the bones

<sup>1</sup> The following should be added to the references cited in our first report: Bamann and Riedel [1934].

<sup>2</sup> Until recently, the Japanese authors of Akamatsu's school divided the phosphatases into phosphomonoesterases, phosphodiesterases, pyrophosphatases and phosphoamidases and claimed to have demonstrated the specificity of the several enzymes. As the whole of our experiments were made with sodium  $\beta$ -glycerophosphate as substrate, the enzymes studied by us should be called, according to the terminology of the Japanese authors, phosphomonoesterases. However, in a recent work by Hotta [1934] it is shown that the specificity of the phosphatases is not determined only by the nature of the bond which unites phosphoric acid to the alcoholic residue but also by the chemical nature of the alcoholic residue itself. Until such time as the question is settled, we prefer to retain the generic denomination of phosphatases.

were freed from the marrow and separate extracts were made of the epiphyses and metaphyses. The phosphatase activity of both extracts was slightly less than that of the corresponding extracts prepared by us for the experiments described in our first paper.

Figs. 1 and 2 show the hydrolysis caused by one and the same extract of rabbit liver at different  $p_H$  values and at different times in the presence and absence of  $M/50$  sodium oxalate respectively.

Fig. 1.

Fig. 2.

Fig. 1. The hydrolysis of  $\beta$ -glycerophosphate in the absence of added oxalate at different  $p_H$  values by rabbit liver extracts. — Hydrolysis in presence of veronal-acetate buffer; ---- hydrolysis in presence of glycine buffer.

Fig. 2. The hydrolysis of  $\beta$ -glycerophosphate in the presence of added  $M/50$  oxalate at different  $p_H$  values by rabbit liver extracts. — Hydrolysis in presence of veronal-acetate buffer; ---- hydrolysis in presence of glycine buffer.

Whilst the curves in Fig. 1 (in the absence of oxalate) show a fairly regular course, those of Fig. 2 (in the presence of oxalate) show a curious phenomenon: at first (from the beginning up to the 3rd hour), the phosphatase activity is seen to be considerably inhibited as compared with the activity developed in the absence of oxalate; later (from the 3rd to the 6th hour) the inhibitory action of the oxalate is no longer manifest and moreover at certain  $p_H$  values the rate of hydrolysis in the presence of sodium oxalate is higher than in its absence. Still later (from the 6th to the 14th hour) the rate of hydrolysis is equal to that observed in the absence of sodium oxalate.

The bone extracts, as may be seen in Fig. 3 (hydrolysis in the absence of oxalate) and Fig. 4 (hydrolysis in the presence of  $M/50$  oxalate), do not show this phenomenon: in the presence of sodium oxalate the rate of hydrolysis decreases more rapidly than in its absence.

In Figs. 1, 2, 3 and 4 it may be seen from the course of the curves in presence of glycine buffer, that in the case of liver extracts the use of glycine buffer leads

to an hydrolysis which is slightly less than that which may be obtained at the same  $p_H$  value when using veronal buffer both in the presence and in the absence of sodium oxalate. On the other hand, in the case of bone extracts, the use of glycine buffer in both cases leads to a much higher hydrolysis.

*The kinetics of the alkaline phosphatases of liver and bone in the absence and in the presence of sodium oxalate.*

Martland and Robison [1927] studied the course of the hydrolysis of sodium glycerophosphate by bone phosphatase in the absence and in the presence of inorganic phosphates. They found that, even without the addition of phosphates, the values of the velocity constant, calculated according to the equation of unimolecular reactions, decreased more rapidly than could be accounted for by the thermal inactivation of the enzyme; they advanced the hypothesis that this phenomenon was due to the process of resynthesis between phosphoric acid and glycerol. They demonstrated the retarding influence of phosphates on the enzymic hydrolysis of glycerophosphate; but, working with phosphate and

glycerol in the concentrations employed in the previous experiments, they did not succeed in demonstrating the possibility of a resynthesis.

Erdtman [1927], using an enzymic preparation of hog kidney, also found that the values of the velocity constant, in the absence of activating agents, rapidly decreased. He attributed this fact, at least in part, to a destruction of the enzyme and to an inactivating action of the products of hydrolysis.

Fig. 5.

Fig. 6.

Fig. 5. The hydrolysis of  $\beta$ -glycerophosphate in the presence and absence of added oxalate by rabbit liver extracts. •—• Hydrolysis in absence of added oxalate; - - - • hydrolysis in presence of added oxalate.

Fig. 6. The hydrolysis of  $\beta$ -glycerophosphate in the presence and absence of added oxalate by rabbit bone extracts. •—• Hydrolysis in absence of added oxalate; - - - • hydrolysis in presence of added oxalate.

Under the experimental conditions habitually adopted by us, we also have found that there is a rapid fall in the values of the velocity constant. However, in agreement with the observations of Němec [1923] when studying the action of soya beans on glycerophosphate, Schütz's law was approximately followed (naturally in the absence of sodium oxalate) with the alkaline phosphatases of both liver and bone.

In Tables I (liver) and II (bone) we give the values of  $k = \frac{1}{t} \log \frac{a}{a-x}$  and of  $k_1 = \frac{x}{\sqrt{t}}$  obtained for a hydrolysis at 37° of sodium  $\beta$ -glycerophosphate, concentration about  $M/100$ , in a glycine buffer in the absence of sodium oxalate, and the corresponding  $k'$  and  $k_1'$  values under the same conditions but in the presence of sodium oxalate.

Table I (liver extract) shows that the values of  $k'$  which at the beginning are very small, tend with time to equal the corresponding  $k$  values and that, while the  $k_1$  values remain constant, those of  $k_1'$  increase greatly at the beginning and then decrease slowly. In Table II (bone extract), on the other hand, the values of both  $k'$  and  $k_1'$  show a progressive and marked decrease with time as compared with the corresponding values of  $k$  and  $k_1$ .

From this it is concluded that the alkaline phosphatase of liver and that of bone differ, in the presence of oxalate, entirely in their kinetic behaviour, whilst the simple examination of the kinetic behaviour of the two extracts in the absence of inhibitory agents might have led one erroneously to conclude in favour of the identity of the two phosphatases.

On increasing the concentration of the substrate, the values of the hydrolysis effected by the phosphatases of liver and of bone no longer conform (even in the absence of sodium oxalate) to Schütz's law. In Table III are given the values of  $k_1$  relative to the hydrolysis of sodium  $\beta$ -glycerophosphate, in concentrations 5 and 10 times that of the previous experiments, for the alkaline phosphatase of the liver and that of bone. In the latter case, there is a decrease in the values of  $k_1'$  which is even more sharply marked.

Table III. *Hydrolysis of sodium  $\beta$ -glycerophosphate in varying concentrations by the alkaline phosphatases of liver and of bone in glycine buffer.*

10 ml. of extract in 50 ml. of total solution.

Extract of rabbit liver values of			Extract of rabbit bone values of		
$k_1 = \frac{x}{\sqrt{t}}$			$k_1 = \frac{x}{\sqrt{t}}$		
Time hours	Glycerophosphate		Glycerophosphate		
	$M/20$	$M/10$	$M/20$	$M/10$	
½	0.0236	0.0286	0.0137	0.0193	
1	0.0221	0.0234	0.0127	0.0164	
2	0.0204	0.0250	0.0112	0.0135	
3	0.0224	0.0243	0.0114	0.0132	

In all probability, by suitably decreasing the concentration of the substrate, the inverse effect may be obtained and therefore also a greater constancy of the  $k$  values.

The attempts made to establish to which of the two types of inactivation described by Michaelis and Rona [1914] that exercised by sodium oxalate on the alkaline phosphatases belongs, *i.e.* whether the inactivation is due to an affinity of the enzyme to the inactivating agent or to an alteration of the "nature of the solvent", did not lead to conclusive results either in the case of the alkaline phosphatase of the liver or that of bone.

*Action of sodium oxalate on the alkaline phosphatase of liver with various concentrations of substrate. Influence of the addition of inorganic phosphates on the hydrolysis of glycerophosphate in the presence of sodium oxalate.*

In order to explain the strange behaviour of the alkaline phosphatase of liver (and, as we shall see later, of kidney) in the presence of sodium oxalate wherein at the beginning there is a strongly marked fall in the hydrolysing power and immediately afterwards the phosphatase activity recovers as if the oxalate were no longer present, two hypotheses could be advanced: (1) that in the extracts of such organs there exist enzymes which are capable of demolishing the oxalate ions; (2) that the reactivating action is due to the products of hydrolysis themselves, that is to say, to phosphoric acid and glycerol.

Determinations of oxalic acid carried out in the course of the hydrolysis led us to discard the first hypothesis. On the other hand, examination of the course of the hydrolysis in the presence of sodium oxalate at varying concentrations of substrate brought important evidence in support of the second hypothesis.

The previous experiments were carried out with solutions of about  $M/100$  sodium glycerophosphate (see Table I); we then experimented with concentrations of glycerophosphate of 5 and 10 times that strength and the results are shown in Table IV.

Table IV. *Influence of sodium oxalate on the alkaline phosphatase of liver with high degrees of concentration of substrate.*

Liver extract 10 ml. in 50 ml. of total solution. Glycine buffer.

Time mins.	Glycerophosphate 0.04672 $M$				Glycerophosphate 0.09344 $M$

180	0.0386	2.67	0.0344	2.38	0.0422	1.46	0.0381	1.33

The hypothesis that an enzyme capable of destroying the oxalate ions is to be found in liver extracts was once again shown to be inaccurate by the experiments made with varying concentrations of substrate. If this were the case, seeing that the quantity of enzymic solution and that of the sodium oxalate used were always the same, the inactivating action of the oxalate should have disappeared in equal times in all cases. Tables I and IV show instead that this period varies from 6 hours to 60 minutes.

Moreover, on comparing the data of Table I (concentration of the substrate about  $M/100$ ) with those of Table IV (concentration of the substrate about

$M/20$  and  $M/10$ ), it will be seen that the inactivating action of the sodium oxalate may be considered as having ceased when the hydrolysis of the substrate has reached percentages of 12, 2 and 1.20 respectively; that is to say, when the phosphorus freed corresponds roughly in all three cases to 0.03 mg. per ml.

The phenomenon of the disappearance of the inactivating action of the oxalate does not therefore depend on the percentage of hydrolysis of the substrate, but corresponds to the freeing of a certain quantity of inorganic phosphorus (or of glycerol), which, for a given enzymic solution used in the same proportions at all times, must be considered as being practically constant.

This quantity of inorganic phosphorus varies directly with the activity of the enzyme and therefore with the "mass" of the enzyme itself.

Table V shows the results obtained when the concentration of the substrate is maintained constant but the quantity of enzymic solution is varied.

The extract of rabbit liver used in this experiment as well as in the succeeding one was different from that used in the previous experiments and was a little less active; consequently the values in Table V and Fig. 7 are not comparable, numerically, with the previous ones.

It will be seen, from Table V, that on using 10 ml. of liver extract the inhibitory action of the oxalate disappears after from 0.0234 to 0.0292 mg. of P per ml. has separated in the corresponding test without oxalate. On using 20 ml. of extract the disappearance of the inhibitory action of the oxalate occurs when from 0.0357 to 0.0414 mg. of P is freed in the corresponding test without oxalate.

Table V. *Hydrolysis of  $\beta$ -glycerophosphate in the presence of sodium oxalate by various quantities of rabbit liver extract.*

Time mins.	Glycerophosphate 0.09344 M. Glycine buffer.			
	10 ml. of liver extract in 50 ml. of total solution		20 ml. of liver extract in 50 ml. of total solution	
	With oxalate $M/50$ $p_H$ 9.38	Without oxalate $p_H$ 9.30	With oxalate $M/50$ $p_H$ 9.21	Without oxalate $p_H$ 9.25
	mg. P hydrolysed per ml.

60	0.0048	0.0202	0.0040	0.0300
90	0.0094	0.0234	0.0045	0.0357
120	0.0295	0.0292	0.0461	0.0414
180	0.0343	0.0348	0.0585	0.0582
240	0.0396	0.0408	0.0686	0.0600

The proof that the disappearance of the inhibitory action of sodium oxalate is due to the inorganic phosphate set free during the hydrolysis is given by the experiment illustrated in Fig. 7.

The four parallel tests were made simultaneously with the same quantity of rabbit liver extract and under the same conditions of concentration of the substrate and of acidity.

Curve *A* represents the hydrolysis of the glycerophosphate in the presence of sodium oxalate  $M/50$  and of disodium hydrogen phosphate added to the extent of 0.03 mg. of P per ml. and, as may be seen, it no longer shows the characteristic course of inactivation with oxalate (*cf.* Fig. 2). Curve *B* represents hydrolysis in presence of the same quantity of inorganic phosphate but in the absence of sodium oxalate.

The two curves practically coincide, curve *A* showing a course which is parallel with and only slightly below that of curve *B*. This means that in

the presence of a suitable quantity of inorganic phosphate the action of sodium oxalate on the alkaline phosphatase of liver is practically nil. Curves *C* and *D* represent the hydrolysis without the addition of inorganic phosphate but in the presence and absence respectively of sodium oxalate. It will be noted

Fig. 7. The hydrolysis of  $\beta$ -glycerophosphate (0.09344 *M*) in the presence and absence of added oxalate and phosphate by a rabbit liver extract (glycine buffer).

Curve *A*  $\bigcirc$ — $\bigcirc$  Hydrolysis in presence of added *M*/50 oxalate and in presence of added *M*/1000 sodium phosphate; *B*  $\bigcirc$ — $\bigcirc$  hydrolysis in absence of added oxalate and in presence of added *M*/1000 sodium phosphate; *C*  $\times$ — $\times$  hydrolysis in presence of added *M*/50 oxalate and in absence of added sodium phosphate; *D*  $\times$ — $\times$  hydrolysis in absence of added oxalate and in absence of added sodium phosphate.

that curve *C* keeps at a much lower level, for the first 90 minutes, than that of *A* and *B*. This means that in the absence of inorganic phosphates the sodium oxalate fully develops its inhibitory activity and then, in the space of 30 minutes, curve *C* rapidly rises until it reaches and almost merges into curve *D* which runs parallel with the two curves *A* and *B* but at a higher level. The difference between the various points of curve *D* and the corresponding points of curve *B* represents the inhibition exercised on the normal hydrolysis of the glycerophosphate, in the absence of other inactivating agents, by the addition of an excess of inorganic phosphate. It is natural therefore that in the test represented by curve *C*, in which this addition was not made, after a certain time the curve itself merges into curve *D* and not, for example, into curve *A*.

It is obvious that the points marked " $\bigcirc$ " in Fig. 7 represent the values of inorganic P determined in tests *A* and *B* less the inorganic phosphate previously added (0.03 mg. per ml.).

#### *Influence of sodium oxalate on the alkaline phosphatase activity of extracts of hog kidney.*

As the statements of Munemura [1933] regarding the influence of sodium oxalate on Type III phosphomonoesterase were made as the result of experiments with an extract of hog kidney, we prepared an extract of hog kidney by following exactly, as Munemura did, Asakawa's prescriptions [1928].

Moreover, a part of this extract was treated with  $\text{MgCO}_3$  and sodium acetate according to the method described by Kurata [1931] in order to separate the

alkaline phosphatase of the kidney from the acid phosphatase. Several experiments were made in parallel and the two extracts, that prepared according to Asakawa's method and that further purified according to Kurata's method were compared.

*Exp. 1.* Date: November 19th, 1934. Glycine buffer.

Extract of hog kidney according to Asakawa

Without oxalate	$p_H$ 8.45	P hydrolysed after $5\frac{1}{2}$ hours	0.1000 mg.
With oxalate $M/50$	$p_H$ 8.67	" "	0.0354 mg.

Extract of hog kidney according to Kurata

Without oxalate	$p_H$ 8.68	P hydrolysed after $5\frac{1}{2}$ hours	0.1023 mg.
With oxalate $M/50$	$p_H$ 8.61	" "	0.0366 mg.

It will be seen that not even the alkaline phosphatase of hog kidney is wholly inactivated by the sodium oxalate.

We would also point out that the extract prepared according to Kurata had not completely lost the acid phosphatase; in fact, on testing the phosphatase activity of this extract on  $\beta$ -glycerophosphate in an acid medium, we obtained the following results:

Extract of kidney according to Kurata (veronal buffer)	$p_H$ 4.75	P hydrolysed after $5\frac{1}{2}$ hours	0.0310 mg.
Extract of kidney according to Asakawa (veronal buffer)	$p_H$ 4.72	" "	0.0762 mg.

In the process of separating the alkaline from the acid phosphatase, Kurata kept the enzyme in the presence of magnesium carbonate in an alkaline medium at  $37^\circ$  for 1 hour. In our previous paper we showed that keeping an alkaline phosphatase at  $37^\circ$  in an acid medium, without any other addition, caused a marked inactivation of the phosphatase. Contardi and Ercoli [1933] have shown that keeping an acid phosphatase (from rice husks) in an alkaline medium causes an inactivation of that phosphatase; so much so in fact that when preparing enzymic extracts from rice husk dephosphorylated with barium hydroxide it is necessary to limit exposure in the alkaline medium to the shortest possible time.

We believe therefore that the mechanism of the separation of the two phosphatases, acid and alkaline, according to Kurata's method, is not exclusively that of adsorption by the magnesium carbonate or the aluminium hydroxide respectively, but that it consists, above all, of an inactivation due to the effect of a  $p_H$  which is unsuitable for the conservation of the enzyme. The recent work of Bamann, Riedel and Diederichs [1934] and of Bamann and Diederichs [1934], who separated the two types of enzymes by keeping the phosphatases themselves in an acid or an alkaline medium for a suitable time confirms this interpretation.

*Exp. 2.* Date: November 22nd, 1934. Glycine buffer.

Extract of hog kidney according to Asakawa.

		mg. of P hydrolysed per ml. after					
	$p_H$	$1\frac{1}{2}$	$3\frac{1}{2}$	$5\frac{1}{2}$	$7\frac{1}{2}$	12 hours	
Without oxalate	8.70	0.0892	0.1667	0.2202	0.2275	0.2342	
With oxalate $M/50$	8.55	0.0333	0.0721	0.1935	0.2096	0.2308	

The sodium oxalate first slows down the speed of hydrolysis to a marked degree. Later on, however, the enzyme recovers its activity as though the inhibiting agent were no longer present.

This experiment again confirms what we said regarding the experiments summarised in Table V, that on increasing the quantity of enzyme, the quantity of inorganic phosphate to be set free before the inactivating action of the oxalate disappears also increases. In the present case that quantity is very large, corresponding with the activity of the extract.

Moreover, the phosphatase activity of this extract, which in the meantime had been kept in the ice-chest at  $p_H$  7.6, had undergone a notable increase as compared with that displayed in the previous experiment<sup>1</sup>.

*Exp. 3. Date: November 26th, 1934.*

The results given in Table VI show that similarly to what occurs with rabbit liver extracts but not with bone extracts (Figs. 1, 2, 3, 4), hydrolysis in the presence of glycine buffer is a little less rapid than in the presence of veronal buffer. It seems moreover that the inhibitory influence of sodium oxalate is greater in the presence of glycine buffer than in that of veronal buffer.

Table VI. *Influence of glycine buffer as compared with veronal buffer on the phosphatase activity of kidney extracts in the presence and in the absence of sodium oxalate.*

Extract of hog kidney prepared according to Asakawa's method. mg. P hydrolysed.						
	Veronal buffer			Glycine buffer		
Time hours	Without oxalate $p_H$ 8.75	Oxalate $M/50$ $p_H$ 8.72	Difference	Without oxalate $p_H$ 8.52	Oxalate $M/50$ $p_H$ 8.72	Difference
1	0.1764	0.1519	0.0245	0.1538	0.1200	0.0338
3½	0.2189	0.1987	0.0202	0.2189	0.1666	0.0523
8	0.2400	0.2222	0.0178	0.2362	0.2069	0.0293

The phosphatase activity of the hog kidney extract during the interval between the second and the third experiments (7 days) was again increased to a most marked degree.

*Exp. 4. Date: November 28th, 1934.*

In all the experiments on hog kidney extract described so far the final concentration of sodium glycerophosphate was about  $M/100$ . Munemura instead worked with a  $M/500$  sodium glycerophosphate. A test made with a concentration of substrate equal to that used by the Japanese author did not confirm his (Table VII) results.

Table VII. *Influence of sodium oxalate on the alkaline phosphatase of hog kidney with  $M/500$  glycerophosphate.*

Extract of hog kidney (the same as that used in the previous experiments but diluted from 1 to 4).

Sodium glycerophosphate  $M/500$ . Glycine buffer. mg. P hydrolysed.

		$p_H$ 8.20	$p_H$ 8.82	$p_H$ 9.07	$p_H$ 9.40
With oxalate $M/50$	After 1 hour	0.0139	0.0250	0.0266	0.0247
	After 2½ hours	0.0222	0.0282	0.0306	0.0315

<sup>1</sup> A similar case was recently observed by Bamann, Riedel and Diederichs [1934] for a liver extract. Bodansky [1932] also found an increase of about 10% in the original phosphatase activity of serum after preservation for 24 hours in the ice-chest. A similar activation of phosphatase was observed by Euler and Ohlén [1911].

*Influence of the addition of inorganic phosphates on the hydrolysis of glycerophosphate in the presence of sodium oxalate by bone phosphatase.*

Fig. 8 represents an experiment carried out in the same way as that described in Fig. 7 but with an extract of bone of young rabbit.

Fig. 8. The hydrolysis of  $\beta$ -glycerophosphate (0.09344 *M*) by a rabbit bone extract in the presence and absence of added oxalate and phosphate.

Curve A  $\bigcirc$ — $\bigcirc$ — $\bigcirc$  Hydrolysis in presence of added *M*/50 oxalate and in presence of added *M*/1000 sodium phosphate; B  $\bigcirc$ — $\bigcirc$ — $\bigcirc$  hydrolysis in absence of added oxalate and in presence of added *M*/1000 sodium phosphate; C  $\times$ — $\times$ — $\times$  hydrolysis in presence of added *M*/50 oxalate and in absence of added sodium phosphate; D  $\times$ — $\times$ — $\times$  hydrolysis in absence of added oxalate and in absence of added sodium phosphate.

In the presence of sodium phosphate added simultaneously with the oxalate, the behaviour is analogous to that of the alkaline phosphatase of the liver.

*Influence on the bone phosphatase of time of contact between enzymic solution and sodium oxalate before the reactivation with inorganic phosphate.*

In order to demonstrate that the oxalate tends permanently to inactivate the bone phosphatase, we placed in three 50 ml. flasks:

	I	II	III
	ml.	ml.	ml.
Glycine <i>M</i> /10	14	14	14
NaOH <i>N</i> /10	6	6	6
Sodium oxalate <i>M</i> /5	5	5	5
Disodium hydrogen phosphate <i>M</i> /20	1	—	—
Bone extract	10	10	10

After 3 hours' digestion at 37° we added:

Disodium hydrogen phosphate <i>M</i> /20	—	1	—
Sodium glycerophosphate 10 % (anhydrous salt)	10	10	10

The contents of the flasks were brought to the mark with distilled water and they were then placed in the thermostat in order to proceed in the usual manner to determine the phosphatase activity. The results, corrected for the quantity of phosphorus added in the form of sodium phosphate, are given in Table VIII.

Table VIII.

	I	II	III
	The oxalate acted for 3 hours at 37° in the presence of added inorganic phosphate	The oxalate acted for 3 hours at 37° in the absence of inorganic phosphate, which was added only after the third hour	In the presence of oxalate but without any addition whatsoever of inorganic phosphate
Time mins.			
30	0.0211	0.0178	0.0078
45	0.0267	0.0202	0.0091
60	0.0308	0.0239	0.0296

120	0.0489	0.0366	0.0400
180	0.0557	0.0416	0.0494

In the absence of added sodium phosphate the oxalate tends permanently to inactivate the bone phosphatase as time proceeds.

#### DISCUSSION.

In our previous work we arrived at the conclusion that aqueous extracts of liver and kidney contain a system of phosphatase enzymes which is different from that of bone extracts and of blood serum. Among the differences encountered was the behaviour in presence of sodium oxalate of the alkaline phosphatase of bone and of serum as compared with that of the alkaline phosphatase of liver and of kidney. In the present work we have carried the study of this behaviour as regards the oxalate ions further and have also arrived at interesting conclusions regarding the general mechanism of phosphatase scission.

Jacobsen [1932], from the work of Martland and Robison [1927] and of Erdtman [1927; 1928] and above all from the results of his own accurate work on the inhibitory action of inorganic phosphates on kidney phosphatase, deduces that in a phosphatase + glycerophosphate system an enzyme-phosphate complex must be formed in addition to the enzyme-substrate complex. The enzyme-phosphate complex, generated by the phosphates freed during the course of the hydrolysis, is, according to Jacobsen himself, inactive. We however demonstrate that this enzyme-phosphate complex has a hydrolytic action on glycerophosphoric acid.

In the experiments described in Tables I, IV and V hydrolysis in the absence of oxalate occurs, at the very beginning of the reaction, according to the now universally accepted general scheme of enzymic actions:

From the tables in question, it may be seen that, in the presence of sodium oxalate, the phosphate freed by the alkaline phosphatase of liver at the beginning of the reaction (0.0055, 0.0084, 0.0047, 0.0045, 0.0038 mg. *etc.*) is much less than that freed contemporaneously in comparative tests in absence of oxalate (respectively 0.0226, 0.0167, 0.0202, 0.0165, 0.0232 mg.). If this fact is interpreted in the sense that the enzyme, besides having affinity for the substrate

has also affinity for sodium oxalate, we must deduce from these data that the division of the enzyme between substrate and oxalate occurs predominantly in favour of the latter, that is to say, in the formation of the two complexes, the first active, the second inactive

the balance is clearly displaced from left to right.

As soon as a small quantity of inorganic phosphate has been freed, we must admit with Jacobsen [1932] the formation of the new complex, enzyme-phosphate, in equilibrium with the previous ones.

Now, in Fig. 7, we have seen that in the presence of sodium phosphate, previously added in suitable quantity, the hydrolysis occurs as if the oxalate were no longer present (curves *A* and *B*), that is to say, the inorganic phosphate impedes the formation of the inactive enzyme-oxalate complex.

This antagonistic action of the phosphate can only be explained by admitting that the enzyme may combine not only with the substrate, but also through a second bond, with other electrolytes. When oxalate unites with the enzyme, there results such a modification in the properties of the enzyme itself that the enzyme-oxalate complex thus formed can no longer be bound to the substrate and is therefore inactive; when instead the phosphate is so bound, the enzyme conserves its property of uniting itself with the other bond to the substrate and of hydrolysing it.

The fact that, as in our case, the inactive enzyme-oxalate complex cannot form in the presence of inorganic phosphates artificially added means that the affinity between enzyme and phosphate is greater than that between enzyme and oxalate and that therefore, out of the two complexes possible, the enzyme-phosphate complex tends to be formed predominantly.

On again examining the action of the alkaline phosphatase of liver on glycerophosphate in the presence of sodium oxalate, it follows from the considerations made that among the complexes which we have admitted exist in the system:

the balance will tend to move in favour of the formation of enzyme-phosphate-substrate. Therefore, as and when, during the course of hydrolysis, the inorganic phosphate is set free, the latter displaces the oxalate from the inactive enzyme-oxalate complex and gives rise to the formation of the active enzyme-phosphate complex<sup>1</sup>.

The demonstration of this process is given by the experiments described in the experimental part (see Figs. 2 and 7, curve *C*) in which the hydrolysis in the presence of oxalate is accelerated as the inorganic phosphate is freed. This acceleration, seeing that the destruction of the oxalate ions was experimentally excluded, can only be attributed to the progressive formation of the active enzyme-phosphate complex at the expense of the inactive enzyme-oxalate complex.

The experiments with hog kidney, made in order to confirm Munemura's statement [1933], allow us to conclude that the mechanism of the action of that phosphatase is identical with that of the phosphatase of rabbit liver. In this case too, therefore, the enzymic action develops at the beginning directly

<sup>1</sup> The fact that the oxalate ions may be easily and completely displaced from the enzyme-oxalate complex has already been demonstrated by us [Belfanti *et al.*, 1935, 2].

between enzyme and substrate; with the gradual formation of the enzyme-phosphate complex, the hydrolysis caused by the latter also comes into play.

The relations existing at the beginning of the reaction between the concentration of the substrate and that of the enzyme will favour in greater or less degree and with greater or less rapidity the formation of the enzyme-phosphate-substrate complex at the expense of the enzyme-substrate complex and according to circumstances the course of the reaction will be more or less removed from that of a unimolecular reaction. In no case however can perfect concordance with this law be expected as the hydrolysis is caused simultaneously by two agents which possess different properties and whose quantitative relations vary continuously with time. In fact, one has to deduce from the experiments represented in Fig. 7 (curves *B* and *D*) that the value of the dissociation constant of the enzyme-phosphate-substrate complex is notably less than that of the constant of dissociation of the enzyme-substrate complex. It is not probable that this is the only difference existing between the properties of the two complexes produced; for example, the complexes may have different acidity optima. In this way one may easily explain several anomalies which are fairly frequently observed in the ordinary processes of enzymic hydrolysis of the phosphoric esters, such as the variation of the optimum of phosphatase activity with the concentration of the substrate [Asakawa, 1928], or during the course of the hydrolysis (Fig. 3).

The considerations discussed in connection with the phosphatase of liver and kidney may perhaps be extended also to other enzymes. One may suppose in fact that the accelerations met with in certain enzymic processes and the abbreviation of the so-called induction period, which may be obtained by adding to the solutions under examination one of the products of the reaction (*e.g.* acetaldehyde in the case of alcoholic fermentation), may be explained by the formation, between enzyme and product of hydrolysis, of a complex which is more active than the free enzyme.

Returning to the phosphatase of liver and kidney, it is probable that the activating action of magnesium, as follows from Erdtmann's work, consists in the formation of a magnesium-enzyme complex which is still capable of uniting with the substrate to hydrolyse it and in which the magnesium is not displaceable by phosphate.

*Phosphatase of bone.* As pointed out by us in the experimental part (Figs. 3, 4 and 6), the phosphatase of bone in the presence of sodium oxalate behaves in a different way from the phosphatase of liver and of kidney. The paralysing action of the oxalate is not limited only to the beginning of the hydrolysis but is manifest during the whole course of the same. In our previous note [Belfanti *et al.*, 1935, 2] we demonstrated that this phosphatase, kept at 37° in an acid medium ( $p_H$  4.5), loses its activity much more rapidly than the alkaline phosphatase of the liver and kidney. Analogously, one may suppose that it is also more sensitive to the action of sodium oxalate and that therefore the formation of the enzyme-oxalate complex is accompanied by a profound alteration of the enzyme, an alteration which occurs gradually during a relatively long period of time and which may lead to the permanent disappearance of the phosphatase activity. One may thus easily explain the fact that the phosphates set free during the course of hydrolysis do not, of themselves, succeed in determining complete reactivation such as occurs in the case of liver and of kidney.

This interpretation of the behaviour of the phosphatase of bone to sodium oxalate is confirmed by the experiment recorded in Fig. 8. For this experiment we purposely used an extract of bone of a young rabbit, recently prepared and

very concentrated, the activity of which was therefore very marked. Hence the time needed in order to free a quantity of inorganic phosphate sufficient to reactivate the enzyme was much shorter and, correspondingly, it became less probable that the enzyme would become permanently inactive. One could hope therefore for at least a partial reactivation of the enzyme by the inorganic phosphate freed during hydrolysis.

In fact, on observing the course of curve *C* (in the presence and in the absence of added inorganic phosphate) one notes at a certain point (between the 45th and 60th minutes) a notable rise in hydrolysing power. Spontaneous reactivation is however very far from being complete. In the case of hydrolysis in the presence of sodium phosphate added at the same time as the oxalate (curve *A*), the behaviour is analogous to that met with in the case of the alkaline phosphatase of liver: in fact, the corresponding curve practically coincides with that of hydrolysis in the presence of phosphate but in the absence of oxalate (curve *B*). This fact may easily be explained because, according to our views, in this case the active enzyme-phosphate complex must be predominantly formed, so that the enzyme is removed from the alterative action of the oxalate.

In order to confirm that the oxalate tends to inactivate the phosphatase of bone in a permanent way, we carried out the experiment recorded in Table VIII (p. 1502). As may be seen, the values in column I are all higher than those of column II. This means that in the first case the formation of the enzyme-phosphate complex has at least in part impeded the permanent inactivation of the enzyme itself by the oxalate. In test II, as the greater part of the enzyme was permanently inactivated, successive additions of inorganic phosphate did not suffice to restore the phosphatase activity of the extract: in fact, the values obtained in this test, except the first two, are markedly inferior to those of test III in which no addition of inorganic phosphate was made. This is natural seeing that the addition of inorganic phosphate slowed down the hydrolysis caused by the phosphatase which was still unaltered.

As a partial conclusion of the work described in this and the previous notes, it may be well to recapitulate our present knowledge of the question of the identity of the alkaline phosphatases.

Robison and Soames [1924], studying the activity of the phosphatases of various animal tissues at different  $p_H$  values, concluded in favour of the hypothesis that the spleen, liver and pancreas contain a phosphatase which is different from that of the kidney and bone. Kay [1928; 1931] from a series of comparisons deduced that the phosphatases of the bones, kidneys, intestinal mucosa and blood plasma are identical. More recently, several Japanese authors of Akamatsu's school [Usawa, 1932; Hori, 1932; Munemura, 1933], after a series of valuable researches, came to the conclusion that the phosphomonoesterases existing in nature may be divided into three types having their optima of activity at  $p_H$  3, 5.5 and 9-10 respectively. The affirmation that all the phosphatases which we have agreed to call alkaline, that is to say, those phosphatases which are capable of hydrolysing the monoesters of phosphoric acid at a  $p_H$  optimum between 9 and 10 inclusive, are identical is implicit in this classification.

From the experiments carried out in the present work, it follows that:

(1) With the phosphatase of bone a hydrolysis is obtained which is much more rapid in the presence of glycine buffer than in the presence of veronal buffer; the contrary occurs with the phosphatase of liver and kidney.

(2) The inhibition caused by oxalate of the phosphatase of liver and kidney is annulled by inorganic phosphate whether this be added artificially or formed in the course of hydrolysis. On the other hand, the inactivation of the phos-

phatase of bone by means of oxalate tends to become permanent so that the phosphates freed during the process of hydrolysis only partially reactivate the enzyme.

In our previous work [Belfanti *et al.*, 1935, 2] we demonstrated that the phosphatase of bone, in contrast with the alkaline phosphatase of the liver and kidneys, is extremely labile in an acid medium.

In correlation with these results, one may recall the fact observed by Hommerberg [1929] that the phosphatase of bone, in contrast with the alkaline phosphatase of the kidneys [Erdtman, 1928] and of the liver [Bamann and Riedel, 1934], is not activated by magnesium<sup>1</sup>. Moreover, according to Hommerberg, the phosphatase of the bone differs from that of the kidney by reason of its greater solubility in alcohol.

The knowledge in our possession is therefore sufficient to allow one to affirm that these are different phosphatases.

The experiments made in the present work were not extended to the phosphatases of the blood and therefore it is not possible for us to make definite assertions on this subject; however, on the basis of the preliminary experiments described in our first report, one may deduce that the phosphatase of blood serum is analogous to that of the bones. The alkaline phosphatases examined by us may therefore be divided into two distinct groups: those of liver and of kidney belong to the first group whilst those of bone and serum belong to the second.

#### SUMMARY.

1. When an extract of liver or of kidney is allowed to act in an alkaline medium on glycerophosphate in the presence of sodium oxalate, the hydrolysis at first proceeds very slowly, then little by little it accelerates and finally proceeds as if the oxalate were no longer present, until the substrate is completely hydrolysed. In the presence of inorganic phosphate added artificially, sodium oxalate does not manifest any inhibitory action whatsoever on the alkaline phosphatase of liver and kidney.

2. It is suggested that the explanation of these phenomena is that the inorganic phosphate set free from the glycerophosphoric acid gradually displaces the oxalate ions from the inactive enzyme-oxalate complex giving rise to an active enzyme-phosphate complex capable, like the free enzyme, of uniting with the substrate and of hydrolysing it.

3. Inorganic phosphates, if previously added, manifest their antagonistic action to sodium oxalate even in the case of the phosphatase of bone. The latter, however, in contrast to the alkaline phosphatase of liver and kidney, when allowed to act on glycerophosphate in the presence of sodium oxalate is incapable of spontaneous reactivation. The probable explanation of this phenomenon is discussed.

4. The kinetic behaviour of the phosphatases of liver and bone was studied.

5. Kurata's process for the separation of the acid phosphatase from the alkaline phosphatase in extracts of hog kidney was examined.

6. The experiments of Munemura regarding the inactivation of the alkaline phosphatases by means of sodium oxalate were not confirmed and the statements of several authors relative to the identity of the alkaline phosphatases of different origin have been discussed. These phosphatases should be divided, for the reasons given in this and our previous papers, into two distinct groups: that of the liver and kidneys and that of bone and probably also of serum.

<sup>1</sup> Kay and Jenner [1931] maintain that the phosphatase of bone is also susceptible to the activating action of magnesium, but only when the latter is present in concentrations of  $M/1000-M/100$ .

CLXXX. ENZYMIC EFFICIENCY IN MALIGNANCY.  
I. INFLUENCE OF THE GROWING WALKER CARCINO-  
SARCOMA ON CONCENTRATION OF BLOOD AND  
TISSUE ENZYMES OF THE ALBINO RAT.<sup>1</sup>

BY BARNETT SURE, MARINUS CORNELIUS KIK  
AND KATHRYN SUE BUCHANAN

(*from the Department of Agricultural Chemistry,  
University of Arkansas, Fayetteville*),

AND HARVEY SHEPARD THATCHER  
AND ALBERT DEGROAT

(*from the Department of Medical Pathology, University of Arkansas, Little Rock*).

(*Received April 5th, 1935.*)

SINCE enzymes are the means by which cancer cells as well as normal cells do their work, and since resistance to malignancy seems to be associated with definite changes in concentration of certain blood and tissue enzymes, it is evident that one of the goals of the biochemist in the study of cancer is to make a systematic and intensive study of all possible factors that influence the concentration of such enzymes with the purpose of preventing the transformation of normal epithelial into cancerous tissues.

Recently we have initiated a detailed study of enzymic efficiency in avitaminosis. Being at the same time engaged in an investigation on the therapeutic effect of vitamins on regression of transplantable tumours in the albino rat, we had the necessary equipment, materials and tumour-bearing animals for the study of enzymic efficiency in malignancy.

EXPERIMENTAL.

In first attempts to transplant tumours, we found our Wistar Institute stock quite resistant to the Flexner-Jobling carcinoma, obtaining only about 50 % of takes. We therefore subsequently used a tumour furnished us by Dr F. C. Wood of the Institute of Cancer Research, Columbia University. This tumour was designated as Walker carcino-sarcoma No. 256, and gave us 60-85 % of takes, provided that the tumour used for implantation was not too necrotic.

The transplantations were made under sterile conditions. The tumour tissue, weighing about 20 mg., was inoculated according to the technique of Suguira *et al.* [1921] with a trocar into albino rats subcutaneously in the region of the right axilla. The animals, about equally divided between males and females,

<sup>1</sup> Research Paper No. 321, Journal Series, University of Arkansas. Supported by a fund from the International Cancer Research Foundation.

A preliminary report of the results of this investigation appeared in the *Proc. Soc. Exp. Biol. Med.* **32**, 658-9, 1935.

were 3–4 months old and weighed 160–200 g. They were given our regular stock diet No. 1, which is composed of cereal grains fortified with caseinogen,  $\text{CaCO}_3$  and  $\text{NaCl}$ . The animals and food were weighed daily.

The experiments were conducted in pairs; for every animal with an implanted tumour a litter-mate control of the same sex was used, which was restricted to the same plane of nutrition as the tumour-bearing animal [Sure *et al.*, 1935]. The tumours were measured, 3 times weekly, with a caliper in length, width and in some cases in depth. 42 groups were studied in the case of most enzymes. The blood serum phosphatase was included later in the investigation and was studied in 31 groups. The tumours ranged from 15 to 73 mm. in length and from 10 to 65 mm. in width. The age of the tumours of the implanted animals, the blood and tissue enzymes of which were studied, ranged from 3 to 5 weeks in most cases; but some individuals were allowed to proceed to the stage of pronounced ulceration and these tumours were about 7 weeks old at the time the animals were sacrificed.

The tumours were embedded in formalin and examined microscopically by Drs Thatcher and DeGroat of the Department of Medical Pathology, University of Arkansas Medical School, Little Rock. The external observations showed cases varying from non-ulceration and slight ulceration to pronounced ulceration with pus oozing from the exterior. On microscopic examination there were present necrosis and inflammation varying from one-tenth to three-fourths of the entire tumour. The following enzymes were studied, all of which were derived from the blood and tissues of the same animal: blood serum amylase, esterase and phosphatase; pancreatic amylase, lipase and esterase; hepatic lipase and esterase; trypsin and erepsin.

The same technique was used for the sampling of blood and the preparation of tissue extracts as has already been described [Sure *et al.*, 1935].

*Methods employed for the determination of the various blood and tissue enzymes.*

The trypsin and erepsin were determined according to the alkalimetric method of Willstätter and Persiel [1925].

For the blood serum esterase the method of Green [1934] was employed, with the following modifications. The amount of blood serum was reduced from 0.5 to 0.25 ml., the amount of ethyl butyrate was increased from 0.25 to 0.5 ml. and the time of incubation increased from 2 to 4 hours.

The pancreatic amylase was determined according to the recent procedure of Ross and Shaw [1934], with the following modification. In addition to the slightly varied technique for the preparation of tissue extract, we used 0.25 instead of 0.5 ml. of the enzyme solution of the pancreatic extract of our concentration [Sure *et al.*, 1935]. Employing our modified technique, we found considerably more amylase units per g. tissue for rats on a normal diet than did Ross and Shaw. Whether this is due to more thorough extraction we cannot say.

The blood amylase was determined precisely according to the same technique as the pancreatic amylase, using 0.25 ml. blood serum in duplicate. In this connection it may be mentioned that all determinations were conducted in duplicate unless there was a shortage of blood serum, in which case only single samples were taken for analysis.

The pancreatic and hepatic lipases were determined according to the technique recently described by us [Sure *et al.*, 1935].

The procedure for the determination of pancreatic and hepatic esterases was changed from our previous technique [Sure *et al.*, 1935] to that employed for blood serum esterase, using 0.5 ml. substrate, 2 ml. of the pancreatic extract, and on account of the large amount of tissue esterase present in the liver, the amount of sample in the hepatic extract was reduced to 0.25 ml. The period of incubation was 4 hours.

The method of Jenner and Kay [1932] for the determination of blood plasma phosphatase was found quite suitable for our determination of blood serum phosphatase, with the following modifications. Instead of 0.25 ml. plasma, we used 0.125 ml. serum; also we employed a period of 2 hours' incubation instead of 3 hours' used by Jenner and Kay.

The results of our investigations are submitted in Tables I-III inclusive. In Table I are presented detailed results of our major findings. In Tables II and III are submitted summarised data of the entire investigation.

## ANALYSIS OF EXPERIMENTAL DATA.

Table I shows that inflammation was found in the majority of the tumours on microscopic examination. We should like to emphasise in this connection that the implantations of tumour tissue were conducted under the most rigid sterile conditions possible. If an infectious organism invaded the tumour-bearing animals, this must have been the result of loss of resistance to infection by virtue of the development of this rapid-growing and necrosing carcino-sarcoma.

The most marked changes were found in the concentrations of blood serum amylase, blood serum esterase and trypsin, showing a reduction percentage in the tumour-bearing animals compared with their litter-mate controls of the same sex and restricted to the same plane of nutrition, of 48.5, 47.0 and 39.0 respectively.

While this work was in progress the paper of Green [1934] appeared, showing the marked decrease in blood serum esterase content of rats inoculated with the Jensen sarcoma. Our results of the blood serum esterase of animals implanted with the Walker carcino-sarcoma No. 256, therefore, concur with those of Green. We did not, however, find such a marked reduction, either in the blood serum or hepatic esterases. The average results of Green expressed as  $N/100$  NaOH for the blood serum esterase are: cancer group, 4.4; normal group, 18.1—a difference of about 400 %. For the liver esterase, the average results of Green are: cancer group, 20.6; normal group, 56.4—a difference of about 175 %. Our tumour-bearing animals showed a reduction in blood serum and hepatic esterases of 47.0 and 16.5 % respectively. The difference in degree of

reduction of these esterases is probably due to the fact that the authors and Green worked with different types of tumours.

Tables II and III show that the reductions in the concentrations of pancreatic amylase, blood serum phosphatase and pancreatic esterase in the tumour-bearing animals are small but definite.

The reduction of 8.7 % in hepatic lipase in the pathological animal is of no significance, since a large percentage of the groups showed increase in this enzyme.

It is of interest to note (as shown in Table II) that considerable reduction in the blood and tissue enzymes of the pathological animals occurred in 76–83 % of the groups.

The changes in the concentration of hepatic lipase, pancreatic esterase and crepsin in the pathological animals are too small to be considered of any value.

It is evident from a careful examination of Table I that there is no absolute relationship between the growth of the tumour, the extent of ulceration, necrosis and inflammation, and the extent of reduction of the concentration of blood and tissue enzymes of the tumour-bearing animals. Because, however, there is a great deal of individual variation in concentration of enzymes in various animals, we have followed up the influence of this growing tumour on the blood serum amylase and blood serum esterase in the living animal, taking two blood samples weekly from the tail of the rat, the purpose being to determine when during the development of the malignancy of this carcino-sarcoma the first enzymic changes begin. Six blood serum amylase and 14 blood serum esterase<sup>1</sup> groups were studied. The results show that pronounced reduction in the concentrations of these enzymes takes place only after the tumour has developed to approximately the 20 mm. size.

The interpretation of our findings will become clearer by a consideration of the recent results of Baló and Lovas [1933]. These investigators studied the enzymes trypsin, lipase and amylase from the pancreas of 70 people who died from different diseases, such as pulmonary tuberculosis, peritonitis purulenta, diabetes, chronic gastric ulcer, haemorrhage of the brain, meningitis, Addison's disease, Basedow's disease and carcinoma. They found in these diseases that the concentrations of the pancreatic enzymes show a parallelism, *i.e.* high lipase content accompanies high trypsin and amylase values; and, in general, when a decrease takes place, all these enzymes are involved. Infectious diseases constitute an exception. The tryptic activity is decreased in the majority of these cases and the lipase and amylase contents remained normal. In diseases where cachexia occurred, a significant decrease of all three enzymes was observed. This decrease was the most pronounced in the tuberculous patients whose conditions led to cachexia. High lipase content was shown to be related to pancreatic fat necrosis.

In our experimental study of rats inoculated with the Walker carcino-sarcoma No. 256, there was no cachexia, since the animals showed no noticeable reduction in daily food intake and since the controls were restricted to the same plane of nutrition as the tumour-bearing animals, the problem of malnutrition was ruled out. The fact, however, that there was a marked reduction in trypsin and only small changes in pancreatic lipase and amylase would indicate that no organism was involved. This agrees with our histological findings of inflammation in most of the tumours examined.

<sup>1</sup> The work on the blood serum esterase was carried out by Miss Thelma James, the results of which constituted partial fulfillment of the requirements for the degree of Master of Science at the University of Arkansas.

The reduction of blood serum amylase would suggest atrophy of the acini of the pancreas, since Elman, using the quantitative viscosimetric method of Elman and McCaughan [1927], has found this to occur in a number of tumour cases [Elman *et al.*, 1929; Elman, 1931]. Our histopathological examinations, however, disclosed only minor changes in the pancreatic tissues.

Our findings of marked reduction of blood serum esterase in the tumour-bearing animals is in accordance with Green's observations in human cancer [1934]. Green, however, found that, where the general health was good, the serum esterase content was on the average slightly higher than in non-cancerous "normal persons", whereas in the terminal stages of cancer it was well below normal, reaching the level observed in acute and subacute bacterial disease.

#### SUMMARY.

Inoculations of the Walker carcino-sarcoma No. 256 subcutaneously into the albino rat produced the following changes in the concentration of blood and tissue enzymes. A marked reduction was observed in the contents of the blood serum amylase and blood serum esterase and trypsin. Small but definite decreases were found in the concentrations of hepatic esterase, pancreatic amylase and blood serum phosphatase. The decreases in hepatic and pancreatic lipase, in pancreatic esterase and in erepsin were too small to be considered of any significance.

# CLXXXI. ON THE ALLEGED AUTOHYDROLYSIS OF VEGETABLE IVORY.

By DANIEL MELNICK AND GEORGE RAYMOND COWGILL.

*From the Department of Physiological Chemistry, Yale University,  
New Haven, Conn., U.S.A.*

*(Received April 12th, 1935.)*

VEGETABLE ivory (*Phytelephas macrocarpa*), the endosperm of the seed of the tagua palm, has long been known as the most convenient source for the preparation of mannose. This sugar occurs in nature in the form of mannans (polysaccharide condensation products) which on acid hydrolysis yield the simple hexose. Approximately 75 % of the vegetable ivory is carbohydrate.

In view of these facts Paton *et al.* [1924] postulated the presence of an enzyme in the ivory nut shavings capable of hydrolysing the insoluble mannans present. The shavings were suspended in water (1-20) and incubated at 45° (optimum temperature) with the addition of toluene to prevent bacterial contamination. A mannose trisaccharide was believed to be first liberated and finally after 10 days only mannose was produced. In neither case was the mono- or tri-saccharide isolated as such; their determinations were solely through formation of corresponding phenylhydrazone and osazone derivatives. Their experiments for enzymic activity may be severely criticised in that no control studies were attempted.

The original purpose of the study reported in the present paper was to investigate the nature of the enzyme and to obtain the liberated mannose, as such, if present at all. However, in the course of the investigation, conclusive evidence accumulated indicating that no mannanase exists in vegetable ivory; and that the presence of a reducing substance in the filtrate is due simply to a warm (45°) aqueous extraction of the nut meal. The carbohydrate responsible for the reducing action of the filtrate was isolated and its properties determined. It is not mannose but apparently a simple derivative of this monosaccharide, which on acid hydrolysis is converted quantitatively into mannose.

## EXPERIMENTAL PART.

### *Attempts to demonstrate the presence of a mannanase.*

In order to demonstrate whether the attempts to purify an enzyme or to augment its activity have been successful, it is essential to have a suitable substrate which can be subjected to the action of the preparations. Possibly a mannan might have been used in our work. However, we preferred to use whole vegetable ivory treated in such a manner as to destroy any enzyme that may be present. Boiling an aqueous suspension of the ivory nut meal for 1 hour, followed by incubation of the filtered material at 105° for 10 days was found to be adequate, in that an additional 10-day incubation of the washed material at 45° in accordance with the method of Paton *et al.* [1924] failed to yield any reducing substance in the filtrate. This material, called "treated" vegetable ivory in this report, was washed free of reducing substance and dried in a vacuum desiccator at room temperature.

Tests for enzymic activity (10-day incubation of the aqueous extract at 45°) were conducted upon washed vegetable ivory meal in the presence of equal concentrations (0.42 %) of toluene, thymol and mercuric chloride. The yield of reducing substance, calculated as mannose, was determined by use of Benedict's [1911] copper titration method. Simultaneously with these, two other experiments, wherein additional equal amounts of treated vegetable ivory were added to the incubation flasks, were carried out. Assuming an enzyme to be present, and 10 days to be adequate for completion of the enzymic hydrolysis [Paton *et al.*, 1924], the addition of an equivalent amount of the substrate to the action of the enzyme in the vegetable ivory should result in the liberation of more reducing substance as compared with the controls. The fact that there was an equal liberation of this compound at the conclusion of the incubations (0.88 % yield, calculated as mannose) argues against the presence of a mannanase in vegetable ivory.

Paton *et al.* [1924] determined the reducing powers of different solutions after 2 hours' incubation by titration with Fehling's solution and constructed a curve from which the optimum  $p_H$  for the enzyme action was read. However, they failed to take into account that merely washing vegetable ivory with water at room temperature yields a filtrate possessing considerable reducing power. Therefore, might it not be possible that the optimum  $p_H$ , as determined by these workers, is merely that for the aqueous extraction of vegetable ivory? In our experiments we had begun with vegetable ivory washed until the runnings were free of reducing substance, so that any additional reducing material obtained upon the completion of the incubation might be attributed to the action of the enzyme.

Might it be possible that during the washings we had also removed the enzyme? If such had been the case, the incubation of "whole" (original unwashed non-heated) vegetable ivory should yield a filtrate containing a greater amount of reducing substance than that liberated in the washed meal *plus* that present in the washings of the meal. Such results were not obtained. An equivalent yield of reducing substance (1.30 %, calculated as mannose) was obtained in both cases. These findings indicate that no mannanase had been removed in the preliminary washing of the ivory nut meal.

Furthermore, the original investigators state that "at a temperature of 60° the action (of the enzyme) appeared to be almost completely annulled". However, we found that the incubation of an aqueous suspension of the nut meal at 65–70° yielded considerable amounts of reducing substance and the addition of washed vegetable ivory to boiling water resulted within 10 minutes in the liberation of this compound; and this occurred at a temperature at which enzymes do not function.

Investigations as to the chemical nature of enzymes have as yet been very indecisive. On the whole, two viewpoints exist. The American school represented by Sumner, Northrop and Sherman, who have prepared crystalline enzymes, advance the conception that enzymes are protein in character. The view of Willstätter's school is that enzymes are composed of a specific active group and a colloidal bearer or carrier and that the specific group binds the enzyme to the substrate.

With these views in mind, we attempted both through standard protein preparations and adsorption technique to secure active fractions or concentrates of the enzyme alleged to exist by Paton and co-workers. A 5 % saline extract of the fat-free meal was saturated with  $(NH_4)_2SO_4$  to precipitate the globulin and albumin fractions. The precipitated proteins were subjected to dialysis in running water for 10 days until a negative sulphate test was obtained, toluene being

used as a preservative. The precipitated globulins were centrifuged off, dehydrated and dried. The supernatant fluid was evaporated to a small volume at 45° and the albumin fraction precipitated by 95 % ethyl alcohol. Whole vegetable ivory has 0.697 % N, equivalent to 4.35 % protein. The globulin fraction (14.2 % N) approximated to a 20 % yield and the albumin fraction (11.7 % N) to a 7 % yield, calculated as percentage of total protein. The protein fractions gave low Kjeldahl nitrogen values, but these determinations were carried out upon the crude products and were not corrected for contaminants.

After a 1-hour extraction at 45° of an aqueous suspension of ivory nut meal buffered at  $p_H$  4.2, 50 g. activated carbon "nuchar"<sup>1</sup> were added and the mixture allowed to stand at room temperature for 2 days. The adsorbate was then decomposed in aqueous medium at  $p_H$  9.2, and the filtrate evaporated to a small volume. The final filtrate apparently contained the proteins described above, giving the characteristic protein colour reactions. Due care was exercised during the preparation of the proteins and adsorbate not to permit the temperature of manipulations to exceed 45°.

The adsorption concentrate and the proteins isolated were tested for enzymic activity, using the treated vegetable ivory as a substrate. No reducing substance was liberated under these conditions.

#### *Isolation and properties of the reducing substance.*

Two kg. of the washed ivory nut meal were suspended in 20 l. distilled water and incubated as described above. After 10 days the filtrate was boiled, filtered and concentrated *in vacuo* to 50 ml., keeping the temperature of the water-bath below 80°. Throughout the concentration, norite treatments and filtrations were necessary to obtain a clear filtrate. The reducing substance was precipitated from solution by daily additions of 20 ml. glacial acetic acid. The final acetic acid filtrate was practically free from reducing substance, indicating that most of the carbohydrate present in the syrup had been brought down. The precipitate was filtered, washed free of acid with 95 % alcohol, dehydrated with acetone and dried in a vacuum desiccator. 19.0 g. were obtained, indicating a yield of 0.95 %.

#### *Properties of the carbohydrate.*

##### Physical:

- (a) Amorphous and hygroscopic.
- (b) Decomposes at 145–155°.
- (c) Mutarotates; at equilibrium  $[\alpha]_D^{25} - 9.62^\circ$ .
- (d) Molecular weight (Beckmann), 183.

##### Chemical:

- (a) Forms glucosazone, m.p. 198°.
- (b) Reducing activity equal to approximately one-third that of mannose.
- (c) On hydrolysis is converted quantitatively into mannose as evidenced by: (1)  $[\alpha]_D^{25}$  of the hydrolysate + 14.75°; (2) recovery of 92.7 % of the material in the form of the insoluble hydrazone (m.p. 188°) and osazone (glucosazone) of mannose (m.p. 198°).
- (d) Elementary composition (sodium fusion tests) indicated no nitrogen or phosphorus to be present, a slight trace of sulphur, which, as sulphate, was probably present as an impurity.

In view of the fact that this carbohydrate possesses approximately one-third the reducing ability of mannose, all yields of reducing substance calculated as mannose, reported above, are actually three times as large. This reducing activity

<sup>1</sup> From the Industrial Chemical Sales Co., New York, N.Y., U.S.A.

may be intrinsic or due to the aqueous hydrolysis of the compound, in that boiling the substance with phenylhydrazine hydrochloride and sodium acetate in appropriate proportions produces the crystalline osazone of mannose (glucosazone). The optical activity of the solutions and the identities of the derivatives (through melting-points and mixed melting-points) were carefully controlled, using crystalline mannose prepared by the method of Hudson and Sawyer [1917] as subsequently improved by Horton [1921], Clark [1922] and Levene [1935].

The water-soluble reducing substance in the cold water extract of the nut meal (preliminary washings) was also identified as being the compound described above.

This carbohydrate has, as yet, not been identified with any reported in the literature.

#### SUMMARY.

1. The presence of a mannanase in vegetable ivory could not be confirmed.
2. During the course of the investigation two new proteins were isolated, namely, albumin and globulin fractions. Further investigation concerning the chemical nature and biological value of these proteins will be undertaken in our laboratory.
3. The reducing substance in the incubation mixtures was isolated and found to be a simple derivative of mannose (probably a simple mannoside or lactone) which on acid hydrolysis is converted quantitatively into mannose.
4. The presence of the reducing substance in the incubation mixture was due merely to its ready solubility in the warm (45°) aqueous extract of the vegetable ivory. The observation that the "treated" vegetable ivory yielded no reducing substance is explained as due to the prolonged heating, followed by washings, resulting in removal of all the water-soluble reducing substance from the outer layer of the particles. This was confirmed by positive reducing tests obtained on the treated nut meal after being reground and incubated at 45° for 10 days.

We wish to express our appreciation to Dr A. White for his most helpful suggestions.

## CLXXXII. THE DETERMINATION OF CHOLIC ACIDS IN BLOOD.

By BERTIL JOSEPHSON.

*From the Chemical Department of the Caroline Institute, Stockholm.*

*(Received April 15th, 1935.)*

MANY methods for the determination of bile acids in blood have been published. Most of them have been tested here and have all been found to give bad results, when small amounts of bile acids were added to the blood. This is due chiefly to two circumstances which interfere with the exact determination; one is the difficulty of separating the bile acids from other blood constituents, and the other is the lack of a specific reaction for the former.

### *General remarks.*

In all methods so far described the proteins are precipitated by treating the blood with neutral alcohol, after which the bile acids are separated from the filtrate and the washings. This precipitation however entails a considerable loss of bile acids, which are carried down with the precipitate and cannot be washed out. This loss is greater for taurocholic and glycocholic acids than for cholic acid. I have been able to avoid loss by precipitating the blood with alcohol to which a certain amount of saturated  $\text{Ba}(\text{OH})_2$  solution has just been added; in this way an alkalinity was reached which was strong enough to prevent precipitation of the bile acids with the proteins but not so strong as to cause solution of alkaline hematin. Barium has also an advantage in its well-known capacity to precipitate the colouring matter of the blood. It is therefore possible even to boil the alcoholic solution containing Ba without obtaining a pigmented filtrate. This ensures a much better extraction of the blood corpuscles and the precipitate than the use of cold alcohol as described by most of the previous investigators. When using  $\text{Ba}(\text{OH})_2$  and alcohol there will appear now and then a colloidal protein-containing suspension (of Ba protein?), which cannot be filtered off. This trouble can be avoided by increasing the Ba concentration, for instance by adding some Ba acetate to the  $\text{Ba}(\text{OH})_2$  solution. Decoloration by aid of  $\text{Ba}(\text{OH})_2$  has been used by several investigators [Aldrich and Bledsoe, 1928; Charlet, 1929; Süllman and Schaub, 1932; Scheinfinkel, 1933; Scott, 1934; Lichtman, 1934], but they all use it after the precipitation with alcohol, when the loss of bile acids has already occurred.

For the final determination of the bile acids different methods have been used. In most methods some modification of the Pettenkofer test is used, that with furfuraldehyde and sulphuric acid having proved to be the best. If the readings are made in more or less monochromatic light in the neighbourhood of the absorption maximum of the characteristic colour (6200 Å. [Gregory and Pascoe, 1929]), the reaction may be considered as fairly specific. Thus Süllman and Schaub used the Pulferich "Stufenphotometer" of Zeiss, and Scheinfinkel spectrographic readings. I have found the use of the "Stufenphotometer" to be the most convenient way for this determination in routine work. If in rare cases the bile acid-containing extract is coloured, or gives a colour with sulphuric acid, this does not prevent the determination, if the same solution without

furfuraldehyde is put into the comparison cup. The slight absorption of the furfuraldehyde itself can be corrected for by subtraction of the reading of a pure furfuraldehyde solution, treated in the same way as the extract. Unspecific absorption with furfuraldehyde generally has little or no effect if the right filter is chosen. I found the most suitable filter to be the S 61, not, as Süllman and Schaub assert, the S 57.

One disadvantage of these colour reactions must be specially pointed out. They are absolutely negative for deoxycholic acid and its conjugates, as has previously been shown by Nakagawa and Fujikawa [1930] and by Reinhold and Wilson [1932]. The numerous statements in the literature that this acid also gives a colour with furfuraldehyde and sulphuric acid must be due to insufficient purification. For this reason it is possible to determine only cholic acid and its conjugates in blood, since all methods of determining the bile acids other than the modified Pettenkofer test give very inaccurate values. For cholic acid and its conjugates, however, the furfuraldehyde test gives very good values. With some modifications the procedure of Gregory and Pascoe proved to be the best. If the readings were made in the "Stufenphotometer", the extinction coefficients found were fairly proportional to the concentration between about 0.1 and 100 mg./100 ml. cholic acid. For cholic, glycocholic and taurocholic acids the extinction coefficient is proportional to the bile acid content (Table I).

The usual statement in the literature, that the reaction is not equimolecular for these different acids, is not correct.

Table I.

2 ml. of	Concentration of acid in mg./100 ml.	Milli- molarity	Extinction coefficient S 61	Extinction coefficient bile salt - extinction coeffi- cient furfuraldehyde molarity bile salt

## EXPERIMENTAL.

*Reagents.*

- (a) Absolute alcohol.
- (b) Saturated  $\text{Ba}(\text{OH})_2$  solution in water with 0.4 % Ba acetate. The bottle should contain some crystalline  $\text{Ba}(\text{OH})_2$ .
- (c) Quartz sand.
- (d)  $\text{H}_2\text{SO}_4$  about 2N.
- (e) NaOH about 2N.
- (f) Ethyl acetate, dried and neutralised if acid.
- (g) Water saturated with ethyl acetate; must be freshly prepared every time, as otherwise the ester will soon be hydrolysed.
- (h)  $\text{H}_2\text{SO}_4$  55 vol. %.
- (i) Furfuraldehyde 1 vol % in water. The furfuraldehyde must be freshly distilled.

Pipettes, carefully calibrated with 5 ml. blood or an exact 5 ml. "Record" syringe, a water-bath kept at a constant temperature of  $65 \pm 1^\circ$ , a good centrifuge, 100 ml. volumetric flasks, an ordinary water-bath *etc.*

Finally special tubes for evaporation and extraction are needed, consisting of an upper part 10–8 cm. long and about 2–4 cm. in diameter connected through a thick-walled constriction with a bulb to hold about 5 ml., the exact 5 ml. mark being in the constricted portion. The whole tube must hold 25–30 ml. The mouth of the tube is provided with a ground glass stopper. The tubes should be made of thick, good glass, so that they stand heating in a boiling water-bath as well as centrifuging at 2000–3000 r.p.m. They must be made to fit in a good centrifuge with about this speed.

Into a 100 ml. volumetric flask containing about 50 ml. absolute alcohol are introduced 2 ml. of the  $\text{Ba}(\text{OH})_2$ -Ba acetate solution; immediately thereafter exactly 5 ml. of the blood which is to be examined are added and the flask is thoroughly shaken. The blood must not contain oxalate or citrate, as these salts precipitate the barium; it is of no importance however whether the blood is defibrinated and taken with pipette or injected with an exact syringe as it comes from the blood vessel. A few grains of quartz sand are then added, and the flask is placed in a boiling water-bath for about 5 minutes. During the first 1–2 minutes it should be shaken to prevent the precipitated protein from sticking to the walls. Neutral alcohol is added after the boiling to nearly 100 ml., and the flask is kept for one day or until the supernatant fluid is clear.

The volume is then brought exactly to 100 ml. and the alcohol filtered off, the first part of the alcohol being allowed to pass the filter two or three times until quite clear and colourless. The precipitate must not be washed, since the bile acids are evenly distributed between the precipitate and the fluid.

The excess of barium is then precipitated with about 0.3 ml. 2 *N* sulphuric acid. When the barium sulphate has flocculated, the solution is again made alkaline to litmus with about 0.5 ml. 2 *N* NaOH. The alcoholic solution is filtered or decanted from the precipitates. The quantity of the filtrate usually reaches 80 ml.

Two amounts of this solution of exactly 30 ml. each must then be evaporated in two of the special tubes and treated as duplicates. The best way is to measure 15 ml. into each tube and to evaporate this amount together with some grains of quartz sand in a boiling water-bath to a few ml. Then the remaining 15 ml. should be added and evaporated until only a few drops remain. Octyl alcohol must not be added during the evaporation, since it will dissolve some bile salt, which then can scarcely be got into aqueous solution.

After the evaporation about 4 ml. of water are added, and the tube is heated again in the water-bath for 10–15 minutes to secure complete solution of the bile salts. The walls of the tubes must be thoroughly washed with the hot water from the lower part of the tubes. When the tubes have cooled, the contents are made strongly alkaline by about 0.5 ml. 2 *N* NaOH. The lipoids must be extracted with ethyl acetate. The alkalisation is necessary to prevent extraction of the bile acids. The ethyl acetate often contains free acetic acid and as the unconjugated bile acids are rather weak, they will be extracted at a slightly alkaline reaction.

To each tube about 10 ml. ethyl acetate are added; the tubes are stoppered and thoroughly shaken three or four times. The stopper is then removed, without unnecessary loss, and the tubes are centrifuged 10–20 minutes until complete separation of the water and ethyl acetate layers is obtained. The lower aqueous layer is then diluted to exactly 5 ml. with water saturated with ethyl

acetate introduced by means of a fine pipette. The tubes are again shaken and centrifuged, and the ethyl acetate together with the thin surface-layer on the water-fraction, consisting of insoluble substances, is sucked off. The aqueous solution fraction is then filtered off or decanted. A slight turbidity does not matter, as it will disappear on treatment with  $\text{H}_2\text{SO}_4$ . 2 ml. of the solution are measured into each of two ordinary test tubes. Into a third tube 2 ml. of a known standard solution of bile acid are introduced (*e.g.* 5 mg./100 ml. cholic acid in diluted NaOH). A fourth tube should contain 2 ml. of pure water. To all the test-tubes 5 ml. 55 % sulphuric acid are added. To one of the two tubes containing blood extract 1 ml. of water is added, and to the other tubes 1 ml. of 1 % furfuraldehyde solution. The tubes are vigorously shaken and placed in a water-bath at  $65^\circ$ . After exactly 20 minutes they are removed and quickly cooled in tap-water. A violet-blue colour in the tubes with furfuraldehyde indicates the presence of bile acids. Very rarely there appears a turbidity, caused by fatty acids, but even if this occurs it does not prevent the reading, since it is similar in the furfuraldehyde tube and in the control.

The solutions are then to be read in the photometer. This should be done within about 30 minutes, as the colour then begins to fade. The blood extract solution with furfuraldehyde should be read against the one without furfuraldehyde as control, the non-significant colours thus being eliminated. The standard and the furfuraldehyde blank are to be read against water. The concentration of bile acids, expressed as cholic acid, may then be calculated according to the usual formula:

$$\text{conc. of unknown} = \text{conc. of standard} \times \frac{\text{ext. coeff. of the unknown} - \text{ext. coeff. of the furfuraldehyde}}{\text{ext. coeff. of the standard} - \text{ext. coeff. of the furfuraldehyde}}$$

For larger series it is most convenient to plot the extinction coefficient values of the furfuraldehyde and of the standard in a coordinate system. The concentrations of the unknown may then be read by plotting their extinction coefficient values on the straight line connecting these two points. The concentration found is 3/10 of that in the original blood sample.

#### DISCUSSION.

To test the accuracy of the method a large number of determinations have been made on defibrinated blood, to which known concentrations of different bile acids had been added. Some few examples of these experiments are given in Table II.

There is a possibility that the distribution of the bile salts between plasma and corpuscles might be different in the addition experiments and in blood from real cases of jaundice. To make sure if the bile acids in the corpuscles were quantitatively extracted by the alcohol and evenly distributed between precipitate and filtrate, the blood from two cases of jaundice, one mild and one severe, was tested. One part of each sample was treated in the usual way, another part was haemolysed with alkali, and thereafter treated like the first. Before and after precipitation with  $\text{Ba}(\text{OH})_2$  and alcohol the excess of alkali was neutralised with the calculated amount of HCl. A third part was also treated like the first, but the precipitate was extracted with alcohol in a Soxhlet apparatus for 5 hours. The extract was added to the first filtrate and the solution then treated in the usual way. Within the limits of the ordinary errors of the method all gave the same value for the respective original blood (Table III).

At concentrations exceeding about 5 mg./100 ml. the method gave values with at the most 6-8 % errors, which were always losses. In most cases the

errors were much less. They were chiefly due to decomposition of bile acids during the evaporation. This could be shown by adding a known amount of bile acids immediately before and immediately after the evaporation to two different tubes with the same extract. The difference between the two tubes was as a rule equal to the usual errors. At lower concentrations however the proportional

errors increased with decreasing concentration, and in normal blood they might be 20 % or even more.

It might be doubted whether the low values found for normal blood really corresponded to bile acids, or whether they were due to some unspecific reaction with the furfuraldehyde. There are, however, some facts indicating that bile acids really were determined. One is the very low normal value for rabbit. It is well known that rabbit bile contains mostly deoxycholic acid and proportionally little cholic acid. It may perhaps be supposed that the same proportions occur in the blood (as mentioned above, deoxycholic acid does not give any colour reaction). There is no reason why rabbit blood should contain less of the substances, giving an unspecific reaction, than blood from other species.

Another circumstance pointing in the same direction is the fact that, if the final aqueous fraction of the blood was treated with lanthanum acetate, every trace of the chromogenic matter was removed. This was not the case if for instance iron, lead or mercury ions were used. This accords with the observation that of numerous metallic ions tested only lanthanum was able to precipitate the bile acids completely both from slightly acid and from alkaline solution.

As a preliminary observation some results may be recorded which were obtained from 19 healthy men, 19–25 years of age. The cholic acid content of the blood varied from 0.6 to 2.2 mg./100 ml., average 1.6 mg./100 ml.

# CLXXXIII. PURIFICATION OF DIPHTHERIA TOXOID.

By PETER JOSEPH MOLONEY AND MORTON DOUGLAS ORR.

*From the Connaught Laboratories, University of Toronto, Canada.*

*(Received April 20th, 1935.)*

METHODS<sup>1</sup> for the purification of diphtheria toxoid may be divided into two classes; those which give a moderate degree of purification and a high yield, and those which give a high degree of purification and a yield which varies within wide limits. Among the latter is the method first applied to toxin by Glenny and Walpole [1915] and later modified by Watson and Wallace [1924] for toxin and by Watson and Langstaff [1926] for toxoid.

The method of Watson and Langstaff depends on the fact that toxoid is precipitated from aqueous solution in the  $p_H$  range 3.8 to 4.4. The precipitated toxoid is in a high state of purity relative to crude toxoid solution but yields may vary with different toxoid preparations from 5 to 90 %.

It seemed reasonable to assume that the low yields which are often obtained by this method might be due not to true solubility of toxoid in the acid solution but either to a slow rate of precipitation or to the presence of substances in the solution which interfere with precipitation. Granting the correctness of either of these suppositions, a toxoid once precipitated should not redissolve in a solution of  $p_H$  3.8 to 4.4. The work which was involved in attempts to prove or disprove this assumption regarding the solubility of toxoid within a certain range of acidity resulted in the methods of purification which are described in this paper. In brief, these methods depend upon precipitation of toxoid in the  $p_H$  range 3.8 to 4.4 by precipitating agents which may also precipitate much other material, followed by removal, under the same conditions of acidity, of the precipitating agent and consequently of other material soluble within the range of insolubility of the toxoid.

## METHOD I.

### *Precipitation by ferric chloride.*

If to a toxoid sufficient ferric chloride solution be added and the reaction of the mixture adjusted to  $p_H$  4.2 a heavy brownish coloured precipitate which contains most of the toxoid is formed. If now a citrate buffer  $p_H$  4.2 in the proper amount be added to the whole mixture the greater part of the precipitate will shortly disappear leaving a small amount of lighter coloured precipitate. The purity of the toxoid contained in this precipitate is of the order of that obtained by the method of Watson and Langstaff but the yields are consistently higher. Various steps in the method will be dealt with under separate headings.

(a) *The amount of ferric chloride required for maximum precipitation.* The results shown in Table I were obtained as follows. 3.5 % ferric chloride solution was added in varying amounts to 50 ml. portions of toxoid solution containing 1 % sodium acetate; the reaction of each mixture was adjusted to  $p_H$  4.2 by the addition of *N* HCl. After about 1 hour the solutions were centrifuged, the supernatant liquids poured off and the precipitates dissolved in water

<sup>1</sup> A fairly complete review of existing methods has been given in a recent paper by Leonard and Holm [1933].

Table I. *Precipitation of 50 ml. portions of toxoid by ferric chloride.*

Ferric chloride ml. 3.5 %	Yield %
0.4	70
0.8	74
1.6	84
3.2	100
6.4	91

by the addition of solid sodium citrate. The amount of sodium citrate added was such as to give a final concentration of 2 %. A short heating at 45° was used to facilitate solution. The toxoid content of the solutions was then determined by the flocculation method. M. L. Smith [1932] had shown that sodium citrate could be used to dissolve the precipitate formed by the addition of alum to toxoid and that such a solution gave a specific flocculation with antitoxin. Citrate can also be used to dissolve the precipitate formed by the addition of ferric chloride to toxoid, and the solution so formed will flocculate specifically with antitoxin. The data given in the table show that for 50 ml. of the toxoid preparation used, 3.2 ml. of the ferric chloride solution were sufficient for precipitation of the toxoid. The minimum amount of ferric chloride required for the precipitation of toxoid varies with different preparations but for the toxoids which we have used it has been found that ferric chloride in the proportion of 1 vol. of 3.5 % solution to 10 vols. of toxoid solution precipitates the maximum amount of toxoid.

(b) *The adjustment of the  $p_H$ .* For convenience in adjusting the  $p_H$  of the toxoid solutions solid sodium acetate was added to a concentration of 1 %. This was done before the addition of ferric chloride and hydrochloric acid. The reactions of the solutions were determined by the spot plate method of Haas [1919] using bromocresol green as indicator. Determinations by this method were checked from time to time by measurements with a glass electrode<sup>1</sup>.

(c) *Citrate buffer. The amount and the manner of addition.* In order to remove iron from the ferric chloride precipitate, a concentrated citrate buffer was used. This was prepared by mixing in the proper proportions the following solutions: (1) sodium citrate 307 g. per litre and (2) citric acid 420 g. per litre. The  $p_H$  of the concentrated buffer prepared from these two solutions was determined after diluting 20 times with water. With the chemicals used by us a mixture in the proportion of 1 ml. of the sodium citrate solution to 0.65 ml. of the citric acid solution gave when diluted 20 times with water approximately  $p_H$  4.2.

In addition to  $p_H$  there are two other factors which may affect the yield of toxoid obtained by extraction of the ferric chloride precipitate with citrate buffer, *viz.* the amount of buffer and the rate at which the buffer is added. In Table II are summarised the results of an experiment on the effect of the addition of different amounts of citrate buffer to toxoid precipitated with ferric chloride. Five samples of a toxoid, 50 ml. each, were precipitated with ferric chloride and adjusted to  $p_H$  4.0. After these solutions had stood for 1 hour different amounts of citrate buffer  $p_H$  4.0 were added quickly and the mixtures kept another hour. The undissolved precipitates were removed by centrifuging, dissolved in water and the Lf values determined. The results in Table II show that the addition of 2 ml. of citrate buffer gave a high yield of purified toxoid and that the addition of larger amounts of citrate buffer resulted in lower yields.

<sup>1</sup> In measuring the E.M.F. of the glass electrode-calomel chain, a circuit arrangement of the type described by V. G. Smith [1934] was used.

Table II. *Effect of citrate buffer on yields.*

Conc. citrate buffer $p_H$ 4.2 ml.	Yield %	Nitrogen mg./Lf
0	95	0.0350
1	95	0.0048
2	95	0.0020
4	79	0.0021
8	75	0.0021

The lower yields resulting from the addition of larger amounts of citrate buffer were found to depend on the rate of addition of the citrate. This is shown by the following experiment. Two 50 ml. samples of toxoid were precipitated with ferric chloride and the  $p_H$  of each was adjusted to 4.2. After 1 hour 16 ml. of citrate buffer,  $p_H$  4.2, were added quickly to one sample and to the other the buffer was added fractionally 1 ml. at a time with an interval of 10 minutes between additions. An hour after the last addition of buffer, the two solutions were centrifuged, the precipitates removed, dissolved in water and the Lf values determined. The results are shown in Table III.

Table III. *Effect on yield of rate of addition of citrate buffer.*

Conc. citrate buffer $p_H$ 4.2 ml.	Manner of addition of buffer	Yield %
16	Quickly	68
16	Slowly	85

The following are the details of the ferric chloride method of purification which we have applied to a number of toxoid preparations.

1 g. of sodium acetate is dissolved in 100 ml. crude toxoid and to this 10 ml. of 3.5 % ferric chloride solution are added;  $N$  HCl is then added to  $p_H$  4.2 and the mixture is kept for 1-2 hours. Next, 4 ml. concentrated citrate buffer,  $p_H$  4.2, are added drop by drop with constant stirring over 30 minutes and the solution is again kept for 1-2 hours. The undissolved precipitate is removed by centrifuging, washed with dilute (1 in 20) citrate buffer  $p_H$  4.2 and dissolved in saline by the careful addition of dilute NaOH to  $p_H$  7.0-7.5. Using the various chemicals in the proportions just set forth, we have successfully applied this technique to relatively large lots of toxoid, up to 17 litres per lot.

It is important to note that the ferric chloride and the citrate should be added to the toxoid in the order given. If, for example, citrate is added before ferric chloride a low yield of toxoid may result.

When purifying large amounts of toxoid we have used a Sharples centrifuge, the bowl of which was lined with cellophane to facilitate the collection of the precipitate.

Table IV. *Yields by ferric chloride-citrate method.*

Lot No.	Yield %	Lot No.	Yield %	Lot No.	Yield %	Lot No.	Yield %

680	85	279	83	609	87	230	86
687	77	643	86	694	100	589	100

Yields obtained by this ferric chloride-citrate method are shown in Table IV and Table V gives a comparison of the yields obtained by acid precipitation and by the ferric chloride-citrate method.

Table V. *Comparison of yields by acid precipitation and ferric chloride-citrate method.*

Toxoid	Acid-pptn.	FeCl <sub>3</sub> -citrate	Toxoid	Acid-pptn.	FeCl <sub>3</sub> -citrate
	Yield %	Yield %		Yield %	Yield %
257	36	95	515	40	100
609	57	87	525	30	85
694	35	100	722	41	94
680	24	100	748	32	100
651	32	100			

Table VI gives data on the composition of purified toxoid obtained from two different toxoid preparations by the ferric chloride-citrate method.

Table VI. *Analytical data for two purified toxoids.*

Yield %	Lf/ml.	Total solids mg./ml.	Ash mg./ml.	Fe mg./ml.	Nitrogen mg./Lf
77	100	2.16	0.065	0.033	0.0022
76	100	0.84	0.22	0.005	0.0007

Other workers have reported values for the nitrogen content of acid-precipitated toxoid ranging from 0.0006 to 0.009 mg./Lf. The data in the table show that toxoid purified by the method described above is as pure as that obtained by the acid precipitation method.

With a few lots of toxoid we have compared the yields obtained with the ferric chloride-citrate method and with the same method in which ferric chloride was replaced by potassium alum. The yields with potassium alum were consistently lower than with ferric chloride.

## METHOD II.

### *Precipitation by acetone.*

The principles involved in this method of purification are the same as those in the ferric chloride-citrate method.

The following are details. Sodium acetate is added to crude toxoid to give 1 % concentration and the reaction of the solution is adjusted to  $p_H$  4.2 with *N* HCl. The toxoid is then precipitated by the addition of 2 vols. of acetone, the precipitate being separated by centrifuging and the supernatant fluid poured off. Part of the supernatant fluid (1/30 vol.) is returned to the precipitate and to the resulting mixture acetate buffer,  $p_H$  4.2, in amount equal to 1/5 the volume of the original toxoid solution is added slowly and with constant stirring. The mixture is kept for 1 hour and acetate buffer is again added in amount sufficient to make the total volume of the acetate buffer equal to one-half the volume of the crude toxoid solution. The small amount of precipitate which remains undissolved is purified toxoid. This precipitate is separated by centrifuging, washed with acetate buffer,  $p_H$  4.2, and dissolved in water with the addition of sodium hydroxide.

If good yields are to be obtained it is important that those substances contained in the acetone precipitate which are soluble in water at  $p_H$  4.2 dissolve

slowly in the acetate buffer. This is accomplished by the technique which has already been described *viz.* by returning some of the acetone supernatant fluid to the precipitate and by slowly adding acetate buffer. Once the water-soluble substances have been removed, the purified toxoid is insoluble in acetate buffer,  $p_H$  4.2.

The importance of the manner of addition of acetate buffer to the acetone precipitate is shown in Table VII.

Table VII. *Extraction of acetone precipitate by two additions of acetate buffer.*

Acetate buffer $p_H$ 4.2		Yield %

Acetone precipitate not extracted		75

The data for this table were obtained as follows: 50 ml. portions of toxoid were precipitated by acetone in the manner already described. The mixtures were centrifuged and the supernatant fluids poured off and to each precipitate were added 5 ml. of the acetone supernatant fluid and the amount of acetate buffer,  $p_H$  4.2, shown in the table under "1st addition." The precipitates were broken up, stirred with the liquid and kept for about 1 hour. Acetate buffer was again added to each mixture to give a final volume of 50 ml. Finally the precipitates were removed by centrifuging and dissolved in saline by the addition of sodium hydroxide.

It should be noted that the final concentrations of acetone and acetate were the same for all the solutions but that the best yields were obtained in those cases in which 4-16 ml. of acetate buffer were first added to the 5 ml. of acetone supernatant fluid.

Table VIII gives results of the acetone method of purification with a number of toxoid preparations.

Table VIII. *Yields by acetone-acetate buffer method.*

Toxoid No.	Yield %	Toxoid No.	Yield %	Toxoid No.	Yield %
272	80	750	74	769	82
680	80	220	73	643	86
717	83	730	94	279	74
939	96	768	82	H.S.	86
749	87				

Diphtheria toxoid may also be purified by a technique similar to that given above, in which ethyl alcohol (5 vols.) is used in place of acetone (2 vols.).

### METHOD III.

#### *Adsorption by ferric phosphate.*

A number of methods have been described for the purification of diphtheria toxin and diphtheria toxoid which depend on adsorption on certain insoluble substances and elution of the adsorbed toxin or toxoid by a suitable solvent [Abt, 1928; Gross, 1929; Ohyama, 1931; Schmidt *et al.*, 1931; Siebenmann, 1932].

Since ferric phosphate is insoluble at  $p_H$  4.2 and since it may be dissolved in citrate buffer we decided to investigate the possibility of the application of the principles already described to the purification of toxoid by adsorption on ferric phosphate.

A suspension of ferric phosphate was prepared by mixing 35 ml. of 3.5 % ferric chloride and 10 ml. of 10 % potassium dihydrogen phosphate and adjusting to  $p_H$  4.5 by the addition of sodium hydroxide. The resulting precipitate was removed by centrifuging, washed twice with acid water,  $p_H$  4.5, and suspended in sufficient saline to give a volume of 70 ml. and the  $p_H$  adjusted to 4.2.

10 ml. amounts of this suspension were added to 50 ml. amounts of four different toxoid preparations to each of which had been added 0.5 g. of sodium acetate. Hydrochloric acid was then added to each mixture to  $p_H$  4.2 and these were kept for 3 hours with frequent shakings. The suspensions were centrifuged and the precipitates washed once with saline,  $p_H$  4.2, and resuspended in 40 ml. of saline. To each of these suspensions 8 ml. citrate buffer,  $p_H$  4.2, were added. The buffer was added slowly 1 ml. at a time with an interval of about 10 minutes between each addition. By this treatment the greater parts of the precipitates were dissolved. The undissolved portions were removed by centrifuging and dissolved in saline by the addition of NaOH to  $p_H$  7.0-7.5.

The yields of toxoid obtained are shown in Table IX along with the yields on the same toxoids purified by the ferric chloride-citrate method.

Table IX.

Toxoid No.	Ferric chloride-citrate	Ferric phosphate adsorption
	Yield %	Yield %
220	100	100
52	75	70
680	85	80
643	80	85

It is of some interest to note that for the particular adsorption complex, ferric phosphate-toxoid, we were able to separate the adsorbed toxoid by dissolving the adsorbing substance leaving the toxoid undissolved rather than by separating the toxoid with a suitable eluent.

Table X gives a comparison of the purifications effected by the different procedures which have been described.

Table X.

Treatment	Yield %	Nitrogen mg./Lf
Original toxoid	—	0.160
FeCl <sub>3</sub> —precipitate	100	0.0518
FeCl <sub>3</sub> ppt.—extracted	93	0.00125
Alcohol—precipitate	93	0.0279
Alcohol ppt.—extracted	73	0.00088
Acetone—precipitate	93	0.0367
Acetone ppt.—extracted	83	0.00111
Ferric phosphate	88	0.00077

It will be seen that the degree of purification is of the same order for all three methods.

## SUMMARY.

Methods of purification have been described by which consistently good yields of diphtheria toxoid in a high state of purity may be rapidly separated from solutions of crude toxoid. These methods consist essentially of precipitation of toxoid by certain precipitating agents and removal from the precipitate of material soluble in the acid range of insolubility of the toxoid.

Toxoids purified by the methods described have been used on laboratory animals both as primary and secondary stimuli. The antigenic response, Lf per Lf, was of the order of that obtained with unpurified toxoids.

We wish to express our appreciation to Dr J. G. FitzGerald, Director of the Connaught Laboratories, for his interest in this work.

# CLXXXIV. THE COAGULATION AND INACTIVATION OF EMULSIN BY HEAT: INFLUENCES OF CRYSTALLOIDAL AND OF COLLOIDAL SOLUTES.

BY DENIS LLEWELLYN FOX AND LOIS LOVELL SORKNESS.

*From the Scripps Institution of Oceanography, University of California,  
La Jolla, California.*

*(Received April 20th, 1935.)*

It was shown by Hanzlik and Butt [1928] that Congo red and certain other colloidal dyes can prevent death in animals injected with otherwise fatal doses of drugs and toxins. Hanzlik [1932] also showed that a certain series of dyes, *viz.* Congo red, vital red, trypan red, mercurochrome, rose Bengal and sodium fluorescein prevented the coagulation *in vitro* of whole serum (horse) or egg albumin on heating to boiling or adding mercuric chloride. Certain other colloids, colloidal dyes, and crystalloidal dyes listed by Hanzlik did not prevent heat coagulation of serum and egg albumin under the same conditions.

The demonstration of the protective action of Congo red and certain other dyes upon egg albumin and tissue extracts was repeated by one of us (D. L. F.) with the same general results as those reported by Hanzlik. Since the addition of certain substances to colloidal systems prevents the radical changes in structure and dispersion which otherwise attend heating, it was thought profitable to investigate the question of whether the function of a colloiddally dispersed protein-containing enzyme could be preserved, in part at least, by adding similar agents to its solutions before heating. Statements have been made to the effect that various anticoagulating agents do not prevent the inactivation of enzymes by various kinds of treatment. Ter Meulen [1905] found that emulsin was protected at 51° by both glucose and lactose, and inhibited only by the former. Waldschmidt-Leitz [1929] cites the work of numerous investigators who studied the inactivation of enzymes, notably Euler and his co-workers who investigated the inactivation of a saccharase by mercuric chloride and the regeneration of the activity by the precipitation of the mercuric ion by hydrogen sulphide. Sucrose was shown to protect saccharase against poisoning by mercuric ion, but not by silver ion. Euler and Myrbäck inactivated saccharase with organic bases and annulled this inactivation by aldehydes, which led to the conclusion that the original inactivation of the saccharase was due to the formation of some kind of aldehyde-amine compound. Haas and Hill [1928] cite the work of several different investigators who studied the restoration to active function of enzymes which had been inactivated by heat; thus Falk brought about the partial recovery of lipase action by the addition of manganese; Biedermann discovered that vigorous shaking with air restored the activity of salivary amylase which had been heated to 100°, whilst Gallagher found that heating the peroxidase of the mangold at 100° for a short interval temporarily destroyed the function of the enzyme, but that it recovered its properties on standing for a time in the cold; the addition of iron and an aldehyde, both of which occurred

normally in the enzyme preparation, was observed to increase the activity of the peroxidase. Space does not permit further discussion here of the numerous experiments upon the inactivation of enzymes by various workers.

In the present work attention was devoted to the possible influences of the hydrogen ion, certain colloidal dyes and two sugars, upon the threshold of heat inactivation of emulsin<sup>1</sup>. In this problem, we have not paid attention to relative rates of inactivation of emulsin at different temperatures and under different conditions, nor have we been concerned with the measurement of the quantity of HCN produced from the hydrolysis of amygdalin by emulsin treated in various ways. We merely measured, as closely as possible by repeated trials, the temperature above which a controlled quantity and concentration of emulsin was inactivated by 30 minutes of incubation. The test for residual enzymic function following heat treatment was made by adding a definite quantity of the substrate, amygdalin, in the same concentration throughout all the experiments, and then incubating the mixture at a moderate temperature (39°), maintaining in the system a sensitive indicator to reveal the formation of any HCN. Two different intervals were employed for this test: 1 hour at 39°, and overnight in the water-bath which was allowed to cool to room temperature during that interval. The substrate employed throughout the work was pure amygdalin<sup>2</sup>. This particular system was employed because there was an obvious advantage in being able to test for HCN, one of the products of hydrolysis, in the air, over the colloidal and usually highly coloured liquid, and thus to determine whether or not the enzyme was still active.

A solution of 1 % amygdalin in boiled distilled water was prepared and kept under toluene as a preservative. A similar solution of 1 % emulsin was prepared, filtered through paper and stored in like manner. The amygdalin solution was shown to remain undecomposed and the emulsin solution to retain its enzymic function for an indefinite period (*i.e.* after several months).

In all cases experiments were conducted in duplicate and repeated if necessary, using mixtures of 1 ml. emulsin solution with 1 ml. of the solution whose protective action was being investigated. In control duplicates 1 ml. of distilled water was added in each case instead of the second solution. The respective volumes were measured by pipette into glass-stoppered cylinders of 10 ml. or 25 ml. capacity, thoroughly mixed, placed in a glycerol-bath, maintained at constant temperature inside a thermostatically controlled electric oven and incubated there for 30 minutes. At the end of this interval the tubes were removed and cooled to 39° by immersion in a water-bath maintained at that temperature by thermostatic control. Then 1 ml. of 1 % amygdalin + 1 ml. of distilled water at 39° were added to the experimental series of incubated emulsin tubes, and thorough mixing was brought about by rapid swirling. The final volume was thus always brought to 4 ml. For the determination of the temperatures at which unprotected emulsin alone was inactivated in the 30-minute pre-heating interval, 1 ml. of 1 % emulsin solution + 1 ml. distilled water only were mixed and subjected in duplicate to the incubation, after which 1 ml. of 1 % amygdalin solution + 1 ml. distilled water at 39° were added as usual. For the regular controls, always conducted along with the experimental runs, provision was made to ascertain whether or not a particular substance which was being investigated for protective capacity exerted any effects upon the hydrolysis of amygdalin itself, irrespective of the previous history of the emulsin: the emulsin was heated with an equal volume of distilled water, the other substances being added at the same time as was the amygdalin, after the incubation period.

<sup>1</sup> Eimer and Amend. C. P.

<sup>2</sup> Coleman and Bell, H. P.

After the addition of the amygdalin solution, the activity of the enzyme was tested for by suspending over the fluid in each tube a strip of alkaline sodium picrate paper (Guignard's test), care being taken that the papers were dry enough to allow no transfer of picrate to the solution below. Guignard's test is, under these circumstances, specific for HCN, which reduces the picrate to picramate, causing the paper to change in colour from lemon-yellow, through orange, to brick-red. For confirmation, use can be made of the silver iodide test developed by one of us [Fox, 1934]. Guignard's test was shown by us to possess a sensitivity of 1 part HCN in 200,000 in a period of 1 hour, and of 1:4,000,000

Table I. *The influences of different solutions upon the temperature of heat inactivation of emulsin.*

in an overnight test. The silver iodide test is simple, absolutely specific, and possesses a sensitivity of about 1:2,000,000.

The main experimental results are incorporated in Table I. Since there was always a short lag in the reattainment of the temperature of the glycerol-bath after the glass cylinders containing the enzyme solutions were placed in it, the 30-minute incubation period was seldom at exactly one unvarying temperature. However, the initial drop and subsequent rise were seldom much greater than 1.5°, and sufficient repetitions were performed to allow such overlapping as to indicate closely the true threshold. The temperatures in the table are therefore very close to the true threshold values, although departures of less than 1° should hardly be regarded as significant. The values of 73° as the upper temperature limit at which 30-minute incubation would permit a subsequent positive test for activity in 1 hour, and 75° as the temperature limit as indicated by a subsequent overnight test, were obtained in repeated checks.

The series of incubations in media of different  $p_H$  values ranging from 1.97 to 8.3 was conducted originally to determine whether small but unsuspected  $p_H$  factors affecting any of the protective experiments would seriously vitiate the results. It is to be noted that only at the low  $p_H$  of 1.97 and at the alkaline values does incubation of the enzyme significantly decrease the inactivation temperature threshold. The optimum range of  $p_H$  values under the conditions of the experiment were thus from about 3.0 to 6.0. The various dyes and sugar solutions did not, as far as could be determined, impart an alkaline reaction to the water in which they were dissolved. The  $p_H$  of the emulsin solution and of the distilled water that was used in preparing the solution was close to 6.0. Whilst all the solutions in both experiments and controls in the  $p_H$  series precipitated to different degrees the incubated enzyme, presumably owing to the presence of the electrolytes, it is of interest to note that at  $p_H$  values of from 6.6 up, the controls (wherein the emulsin was incubated in distilled water, the buffer being added only at the time that the amygdalin was introduced for the activity test) showed no precipitates, the amygdalin presumably protecting the enzyme from precipitation at the higher  $p_H$  values during the test.

Congo red, a colloidal dye which prevents the coagulation of heated egg albumin solutions, did not raise the inactivation temperature of emulsin, but actually lowered it considerably when solutions of 1 % of the dye were added to the enzyme solution before the heating. As the concentration of the added dye was successively decreased, the degree of lowering of the inactivation temperature of the enzyme was steadily decreased in proportion; the presence of 0.001 % of the dye exerted perhaps a slight protective influence. None of the Congo red solutions affected the hydrolysis tests in control experiments.

Fluorescein and rose Bengal, colloidal dyes which also prevent the coagulation of heated solutions of egg albumin, not only failed to protect the enzyme against inactivation by heat, but increased its sensitivity, so that the inactivation temperatures with either dye present were considerably lower. Both of these dyes also exerted inhibitory influences on hydrolysis in the controls. The same was found to be true of neutral red, a dye which does not prevent the heat coagulation of albumin.

The colloidal dyes Congo red, fluorescein and rose Bengal, as would be expected, produced no HCN from amygdalin when mixtures of the glucoside and the respective dyes were incubated for several days.

Lactose at a concentration of 1 % exerted no measurable effects upon the temperature of inactivation, nor did it interfere with hydrolysis. Higher con-

centrations of lactose were not employed since this sugar, being a  $\beta$ -glucoside, is hydrolysed by emulsin, and yields glucose as one of the products.

Glucose, one of the by-products of the hydrolysis of amygdalin, was observed to exert a certain degree of protective action at various concentrations, causing tolerance toward slightly higher temperatures of incubation. The highest concentration of glucose employed exerted a slight retarding effect upon the hydrolysis of amygdalin in the controls, heated in the absence of the sugar. This is taken to signify that solutions of the enzyme heated to the usual threshold of  $73^{\circ}$  possess insufficient active enzyme to bring about perceptible hydrolysis in the 1 hour period, in the presence of this concentration of glucose, thus accentuating the protective influence of the sugar upon the enzyme heated in its presence. Whether or not the glucose exerted its protective action by virtue of its aldehydic properties was not ascertained.

In general, electrolytes or non-electrolytes, present in true solution, brought about varying degrees of precipitation of the enzyme when this was incubated in their presence. Amygdalin prevented any precipitation of the enzyme in control experiments at  $p_H$  values from 6.6 to 8.3, but not in the range from  $p_H$  6.0 down to  $p_H$  1.97. The enzyme alone in distilled water was not precipitated from solution at the inactivation temperatures, nor were enzyme solutions in the presence of the dyes so precipitated, with two exceptions: rose Bengal in final concentrations of 0.25 % brought about precipitation even in the presence of amygdalin, and the weakest solutions of Congo red (final concentration 0.00025 % or below) brought about the same results. These precipitations occurred probably as a result of mutual neutralisation of colloidal charges near the range of sensitisation of the dye.

While the lactose and glucose solutions all showed a precipitating influence upon the heated enzyme, nevertheless the inactivation temperature was either raised or left unchanged in all instances.

There is apparently little if any direct relationship between the heat inactivation and heat coagulation of emulsin under the described conditions. That inactivation of the heated enzyme occurred through a reaction involving water was demonstrated by heating the dry, powdered emulsin for half an hour to temperatures as high as  $150^{\circ}$ , without destroying its function. Heating the enzyme in absolute alcohol to the boiling point of the latter ( $78.4^{\circ}$ ), or in glycerol to  $100^{\circ}$  for half-hour periods did not destroy its activity as did heating to these temperatures in water.

#### SUMMARY.

1. Pure emulsin in dilute aqueous solutions was inactivated by incubation for 30 minutes at an upper limit of  $75^{\circ}$ , although the enzyme was not precipitated at the inactivation temperature.

2. Solutions of fluorescein and Congo red, each of which at a final concentration of 0.5 % prevents the heat coagulation of egg albumin or serum proteins, failed to advance the temperature threshold of the heat inactivation of emulsin; on the contrary, these solutions increased the sensitivity of the enzyme to heat, and lowered the inactivation temperature, as did neutral red, a colloidal dye which does not protect proteins against coagulation by heat. Very dilute solutions of Congo red (0.00025 % and below), while protecting emulsin to only a slight degree, if any, brought about a degree of mutual precipitation of enzyme and dye.

3. The action of rose Bengal upon emulsin was not determined, since this dye interfered with the hydrolysis in the controls.

4. Incubation of emulsin in solutions adjusted to various  $p_H$  values exerted significant depressing effects upon the temperature threshold of the enzyme only at  $p_H$  values as low as 1.97, and at 7.65 and above. With increasing alkalinity the enzyme was destroyed by incubation at successively lower temperatures. The rate of hydrolysis of amygdalin in the controls was not retarded until solutions at  $p_H$  6.6 and above were employed.

5. A 0.5 % lactose solution was without appreciable influence upon the inactivation temperature of emulsin.

6. Glucose solutions from concentrations of 25 % down to 2.5 % protected emulsin somewhat against heat inactivation, the higher concentrations raising the threshold temperature several degrees. 25 % glucose exerted a slight retarding effect upon the rate of hydrolysis in the controls.

7. The emulsin was precipitated to varying degrees when incubated with crystalloidal solutes such as dilute acids, phosphate buffers or sugars.

8. With the exception of rose Bengal and the weakest of the Congo red solutions, the dyes when incubated with emulsin did not precipitate it.

9. There was apparently little if any direct relationship between the heat inactivation and heat coagulation of emulsin under the conditions of the experiments.

10. It would seem probable that emulsin forms a compound or "sorption complex" of some kind with glucose, a product of the hydrolysis of the substrate, which is capable of protecting the enzyme to a certain degree against destruction by heat.

11. Heating emulsin in the absence of water (*i.e.* in dry, powdered form to temperatures as high as 150°, in absolute alcohol to 78.4°, in glycerol to 100°) did not destroy the enzyme's function as did even lower temperatures in the presence of water.

# CLXXXV. PROBLEMS OF NITROGEN CATABOLISM IN INVERTEBRATES.

## IV. THE SYNTHESIS OF URIC ACID IN *HELIX POMATIA*.

By ERNEST BALDWIN.<sup>1</sup>

*From the Biochemical Laboratory, Cambridge.*

(Received April 27th, 1935.)

IN the third paper of this series [Baldwin, 1935] it was pointed out that there exists among gastropods a marked correlation between the presence of arginase and the production of uric acid. Both arginase and uric acid are abundantly present in terrestrial forms, and Needham [1935] believes that the production of uric acid as the main nitrogenous end-product is an adaptation to terrestrial life, just as it is believed to be in the insects, birds and some reptiles. Whether uricotelic metabolism and the possession of arginase are independent or linked concomitants of the adaptation to terrestrial habitat is not clear, but the fact that the correlation holds even for such apparently aberrant cases as that of *Arion* suggests that arginase may actually participate in the synthesis of uric acid.

In all animals hitherto examined a high arginase activity goes hand in hand with a cyclical synthesis of urea [Krebs and Henseleit, 1932; Manderscheid, 1933]. The arginase content of the hepatopancreas of *Helix pomatia* is actually of the same order as that of the most active of mammalian livers [Baldwin, 1935], and by analogy it might be suggested that in *Helix*, as in the mammals, arginase is primarily concerned with the synthesis of urea. Baldwin and Needham [1934] attempted to demonstrate such a synthesis on the part of surviving slices of the hepatopancreas and were unsuccessful, but their negative results would be explicable if urea were in some way removed as fast as it was formed. This possibility remains open; destruction of the urea by a urease seems however to be ruled out since no evidence could be found for the presence even of traces of that enzyme in the hepatopancreas.

Now Wiener [1902] has suggested that, in the case of the bird, uric acid may arise from urea according to the following scheme:

<sup>1</sup> Senior 1851 Student.

This view received a little experimental support from the perfusion experiments of Meyer and Jaffé [1877], Wiener [1902] himself, and Izar [1911]. Friedmann and Mandel [1908] however obtained negative results, and in more recent times the perfusion method has yielded only negative results in the hands of Russo and Cuscuna [1931] and of Cuscuna [1934]. Benzinger and Krebs [1933] and Schuler and Reindel [1933] have obtained negative results with the tissue slice technique and the subject has also been extensively studied by workers of the Italian school. Urea was injected into birds (hens, geese, pigeons), the following substances being orally administered at the same time: malonic, tartronic and lactic acids [Clementi, 1929]; pyruvic and propionic acids [Torrissi and Torrissi, 1931]; dialuric acid [Torrissi, 1932]; glycerol and glyceric acid [Biondi, 1932]; tartronic, lactic, barbituric and dialuric acids [Russo, 1933; 1934]. In no case was any significant increase in the output of uric acid recorded, while in some of the experiments the urea was quantitatively recovered. Clementi [1930] concluded that only ammonium carbonate has any influence on the uric acid excretion, while that of urea is only affected by arginine [Clementi, 1932], and Needham *et al.* [1935] have shown that this is true also for the chick embryo. There can thus be no doubt that Wiener's scheme is entirely inapplicable to the avian organism, if only because the avian liver is unable to synthesise urea [Manderscheid, 1933].

Schuler and Reindel [1933] have found that in the Columbidae the liver and the kidney act successively in the production of uric acid, the liver producing a non-purine precursor which the kidney then converts into uric acid. Baldwin and Needham [1934] made use of this fact to find out whether the synthesis of uric acid follows the same path in the snail as in the bird, and concluded that the respective mechanisms must be quite different. Consequently there is no *a priori* reason for believing that Wiener's scheme, inadmissible as it may be for the case of the bird, is necessarily excluded in that of the snail. Wolf [1933] in fact claims to have shown that a hepatopankreas *brei* prepared from *Helix pomatia* is able to produce uric acid from urea under certain conditions, but his technique and results are open to serious criticism [Baldwin and Needham, 1934].

The present paper reports the results obtained in a study designed to test the possibility that urea may be convertible into uric acid in *Helix pomatia*, since, if this were the case, it would go far towards explaining the observed correlation between the presence of arginase and a uricotelic metabolism in the gastropods. The results are necessarily of a preliminary nature; the main problems of technique have been solved and a tentative working hypothesis is put forward. Further experiments will be carried out as soon as the material again becomes available.

#### EXPERIMENTS.

The method employed consisted essentially in allowing surviving slices of the hepatopankreas of well-fed specimens of *Helix pomatia* to act upon a solution containing possible precursors and seeing whether any more uric acid was produced than in control experiments. In order to find the rate of synthesis it was necessary to determine also the preformed uric acid content of a further sample of the slices.

Some experiments were first done in which no attempt was made to extract uric acid from the tissue itself. The slices were simply suspended in a suitable Ringer solution to which galactose had been added and shaken under standard conditions for 5 hours. The experimental slices received in addition 0.3–3 mg. urea or the same quantity of urea and tartronic acid, but these substances were of course omitted from the controls. After shaking the flasks were

placed on a boiling water-bath, the proteins precipitated by adding uranium acetate and the fluids filtered. Uric acid was then estimated in the filtrates and the following results were obtained:

Substance added	No. of Exps	mg. uric acid synth. per g./hr.	Increase	% Increase
Controls	—	0.0327	—	—
Urea and tartronic acid	4	0.0686	0.0359	109
Urea alone	3	0.0465	0.0138	42
Tartronic acid alone	3	0.0413	0.0086	26

Although only very approximate, these data served to show the desirability of pursuing the question.

Two main difficulties were encountered in developing the technique. In the first place the cells of the hepatopancreas contain solid concretions of uric acid (see Strohl's review in Winterstein [1914]) and it was necessary to find a method for extracting and estimating this intracellular uric acid. Simple procedures such as grinding with sand, extraction with lithium carbonate *etc.* proved unsatisfactory and the method finally adopted was the following. The tissue, usually about 1 g. moist, was placed in a small mortar and thoroughly ground with two drops of octyl alcohol; sand was added and the grinding repeated. Then 5–10 ml. of Benedict and Hitchcock's [1915] phosphate mixture were added, the whole well mixed and the sand and fragments of tissue allowed to settle. The supernatant suspension was decanted and the residue again ground up, treated with phosphate mixture, again allowed to settle and the supernatant again decanted. The residue was ground a third time and finally washed into the combined supernatants with more of the phosphate mixture. About 25 ml. of the latter were used altogether. The whole mixture was digested on a boiling water-bath for 25 mins., 7 ml. of 1.55 % uranium acetate were then added to precipitate proteins and the digestion was continued for a further 5 mins. The whole was now filtered into a measuring cylinder, the precipitate being returned to the flask and digested for 10 mins. with a further 10 ml. of phosphate mixture, again filtered and finally washed on the filter-paper with 5 ml. of phosphate mixture. In this way crystal-clear yellow filtrates were obtained which contained practically the whole of the uric acid. Samples were taken for the estimation of uric acid by the method of Folin [1930; 1933]; the standard solution always contained 0.02 mg. uric acid and the comparisons were effected with a Klett top-reading colorimeter.

The second difficulty arose in preparing Ringer solutions in which any appreciable synthesis of urea from urea and tartronic acid could be demonstrated. The results described above were obtained using a Ringer having the composition described by Baldwin and Needham [1934], but when new solutions of the same composition were prepared the "extra" synthesis resulting from the addition of urea and tartronic acid seldom exceeded 10–20 % of the "basal" synthesis which was always found, even in the controls. Following a hint previously given by Prof. H. Cardot the solutions were next made up in freshly prepared glass-distilled water and a marked improvement was found at once. It is probable that the ordinary distilled water of the laboratory contains traces of copper but that this had been precipitated from the solution used in the first experiments, since this had been made up some weeks before it was actually used. Two Ringer solutions were used; one, containing bicarbonate, was used as a medium for the suspension and shaking of the tissue slices, while the second, which was unbuffered, served to wash the tissues. Both had a calculated freezing-point depression of 0.31° and were therefore isotonic with the blood of fed

waking snails [Duval, 1930; Kamada, 1933], and the composition, given in Table I, followed that recommended by Bernard and Bonnet [1930].

Table I.

	g./litre	
	Ringer I	Ringer II
NaCl	1.16	2.84
NaHCO <sub>3</sub>	2.43	—
KCl	0.344	0.344
CaCl <sub>2</sub> , 6H <sub>2</sub> O	1.75	1.75
MgCl <sub>2</sub> , 6H <sub>2</sub> O	2.56	2.56

Ringer I was saturated with CO<sub>2</sub> before use and Ringer II with oxygen. The  $p_H$  of the bicarbonate Ringer when equilibrated with 5 % CO<sub>2</sub> at 28° was 7.7 which is the same as that of the haemolymph of well-fed waking snails [Baldwin and Needham, 1934], and the suitability of these solutions was shown by the fact that isolated hearts of *Helix pomatia* could be maintained in an actively contractile state for periods of at least 20 hours, *i.e.* at least four times as long as the projected experiments.

Urea and tartronic acid were added in the form of a solution containing 30 mg. of these substances per ml. and previously neutralised. Fresh solutions were frequently made up since a heavy growth of bacteria or mould usually appeared in a day or two.

The following procedure was adopted in all the experiments. Slices were prepared from the hepatopancreases of 5–7 well-fed snails. They were washed three times with Ringer II, divided into four approximately equal portions, freed from surplus water and weighed. Meanwhile four flasks of the type used by Krebs [1933] had each received 10 ml. of Ringer I and 100 mg. galactose [see Baldwin and Needham, 1934]. A gas mixture containing 5 % CO<sub>2</sub> and 95 % O<sub>2</sub> was passed through in order to bring the  $p_H$  to the required value, the tissue was dropped in and the flasks were placed in the thermostatic bath, which was electrically maintained at 28°. The flasks were usually shaken for 5 hours in all, the gas mixture being passed in for the first 20–30 mins. One flask was retained for the determination of the preformed uric acid content of the slices, a second served as a control and the other two received the substance or substances the effects of which were to be tested. At the end of the period of shaking the slices were removed from the flasks by means of forceps and ground up *etc.* in the manner already described, the extracts being added to the suspension fluid.

It should be mentioned in passing that some fragmentation of the tissue always took place as a result of shaking, although the greatest care was taken to ensure smooth running of the shaking machine. Consequently it is likely that the observed rates of "extra" synthesis were smaller than those obtaining *in vivo*.

## RESULTS.

The protocol of Table II gives data obtained in a typical experiment. By "extra" uric acid is meant the amount formed in the experimental flasks over and above that found in the controls. The amounts of urea and tartronic acid added were usually 3 mg. each, which are equivalent to about 4.2 mg. uric acid, so that the yields shown in the protocol ("extra" uric acid) represent 5.2 and 4.4 % of the theoretical yields. These, though small, are certainly significant since in some experiments where the theoretical yields were only 0.3 mg. uric acid, the actual yields were still about the same, 0.15 mg., representing about 50 % in this case. It is probable that the tissue, working at its full capacity, can synthesise

Table II.

Apparatus	1	2	3	4
ml. Ringer I	10	10	10	10
mg. galactose	100	100	100	100
mg. urea added	—	3	3	—
mg. tartronic acid added	—	3	3	—
mg. uric acid found	0.625	0.728	0.632	0.374
Therefore mg. uric acid/g. tissue	0.790	1.010	0.974	0.448
Therefore mg. uric acid synth./g.	0.342	0.562	0.526	—
mg. "extra" uric acid/g. in all	—	0.220	0.184	—
mg. uric acid synth./g./hr. — R	0.0662	0.1020	0.0956	—
% increase in R	—	62	54	—

about 0.15 mg. uric acid per g. in 5 hours from urea and tartronic acid, and that it is impossible to force the pace simply by adding more of the precursors. This point is important since the production of uric acid from urea and tartronic acid is known to take place *in vitro* under suitable conditions [Wiener, 1902], but it is evident that the change observed in the present experiments is associated with the presence of the tissue and is not merely an uncatalysed reaction taking place *in vitro*.

It seems likely that the "basal" synthesis which was observed in the controls is due to xanthine oxidase. That enzyme is known to be present in the hepatopancreas of *Helix* [Przylecki, 1926; Baldwin and Needham, 1934] as are its substrates also [Wolf, 1933]. Furthermore it was found that this basal synthesis persisted even when the Ringer solutions were unsuitable for the demonstration of any "extra" synthesis, that it appears to be independent of  $p_{\text{H}}$  over a range of about 6–8 (within the limits of experimental error), that it continues even in *brei* and is not completely abolished by  $M/10$  NaCN. An attempt was made to demonstrate the presence of xanthine oxidase by means of the methylene blue technique, but as blanks carried out on unwashed *brei* already had a reduction time of many hours it is not surprising that this attempt failed. The hepatopancreases of 10 snails were finely ground, extracted several times with Ringer II and the extract centrifuged. The centrifugate was then saturated with ammonium sulphate and filtered at the pump. Concentrated solutions of the precipitate were tested for xanthine oxidase by the methylene blue method but the reduction time again ran into many hours. Further attempts will be made to concentrate the enzyme, but meanwhile it is not unreasonable, in view of the existing evidence, to attribute the basal synthesis to the operation of the xanthine-xanthine oxidase system.

The results obtained in experiments in which urea (U) and tartronic acid (T) were added are summarised in Table III and, in graphical form, in Fig. 1. A glance at Fig. 1 shows that there is considerable variation in the rates of synthesis, and on comparison with Table III it will be seen that the variation is greatest in the experiments in which the preformed uric acid is greatest. The extra synthesis is determined as the difference between the final uric acid contents of experimental samples and the corresponding controls, and the basal synthesis as the difference between the initial and final uric acid contents of separate controlling samples. Consequently in comparing the rates of synthesis in control and experimental samples we involve a cumulative error which may be very large on account of the initial errors due to sampling, and these may themselves be large.

Table III shows that the preformed uric acid may vary from 0.1 to 1 mg. per g. tissue, and each sample here represented 6 snails on the average. The indi-

vidual variation must probably be still greater. Some determinations were made in order to evaluate the probable error due to sampling and the results are

Fig. 1. Rates of synthesis of uric acid from urea and tartronic acid. (The numbers refer to the actual experiments and A to the averages of the various groups. Note that the addition of urea alone has no appreciable effect.)

	0.124	+4.2
	0.110	-7.6
	0.121	+1.7

Mean variation from group average =  $\pm 5\%$ .

In order to reduce the sampling error as far as possible the snails used in any given experiment were taken from a batch which had been awakened and kept in a uniform manner for the same length of time, but beyond this no standardisation was possible, and it was not feasible to reduce the sampling error any further. To work on only one snail, assuming that the uric acid concretions are uniformly distributed, would have made the scale of operations too small, while the alternative procedure of using a large number of snails was rejected since the preparation of slices from only 6 animals usually took at least  $1\frac{1}{2}$  hours and longer waiting would certainly have been detrimental to the tissues. It was therefore necessary to accept the results as they came and to average as many data as could be obtained.

Although there is in individual cases a considerable range of variation between the rates of synthesis in the controls the average results for the two sets of controls are in excellent agreement and it is therefore unlikely that the rates of extra synthesis are seriously in error. At least five times as much uric acid was produced, on the average, when tartronic acid was present as when urea was present alone, and the results are still more striking if we compare the rates of synthesis with and without tartronic acid with the average rate of all the controls instead of with the group averages as in Table III. We then get the following:

	R	% increase in control
Controls	0.0553	—
Urea alone	0.0577	4.3
Urea and tartronic acid	0.0856	55.0

We do not know whether tartronic acid is a normal metabolite or whether it is replaceable by other 3-carbon compounds such as lactic acid. It is proposed to study these questions in future experiments. But in any case there can be no doubt that urea and tartronic acid are together convertible into uric acid by surviving slices of the hepatopancreas of *Helix pomatia*.

Such an arrangement would probably be a very convenient one from the point of view of the snail itself. Activity is associated, as Howes and Wells [1934] have shown, with high water content, and probably therefore with a flow of water through the body. If urea is synthesised from the products of protein catabolism it can be passively washed out of the body, even if no process of active secretion is brought into play, and Baldwin and Needham [1934] have already suggested that "diuresis" may play an important part in the elimination

of urea from the body. When the water current ceases the animal either aestivates or hibernates, according to the conditions, and becomes in effect a closed system reminiscent of the cleidoic egg. Urea can no longer be washed out of the body and its conversion into uric acid would obviate a twofold toxæmia; first, simple uræmia—and to judge by the data given by Wolf [1933] there is actually no great accumulation of urea during hibernation—and secondly the ammo-næmia which might be produced by the action of the nephridial urease [Przylecki, 1922; Baldwin and Needham, 1934] upon accumulated urea.

As a working hypothesis, then, it seems not unreasonable to suppose that urea is synthesised in *Helix* by means of the ornithine cycle, which of course involves arginase, and is then further converted more or less completely into uric acid, probably by way of dialuric acid, the degree of conversion depending upon the condition of the animal. Such an hypothesis is in no way excluded by any of the known facts, it explains the observed correlation between arginase and uricotelic metabolism in the gastropods, and it appears to stand the test of biological fitness. Further work is necessary to establish the truth or otherwise of the hypothesis in the special case of *Helix* before its applicability to the gastropods as a whole can be considered, and further experiments will be carried out as soon as the material again becomes available.

#### SUMMARY.

Urea and tartronic acid are together convertible into uric acid under the influence of surviving slices of the hepatopancreas of *Helix pomatia*. The significance of this finding is discussed in the text.

The author is glad to express his indebtedness to the Royal Commissioners for the Exhibition of 1851 for a Senior Studentship during the tenure of which this work was done.

# CLXXXVI. THE INTERFERING ACTION OF GLUTATHIONE IN THE SILVER NITRATE TEST FOR ASCORBIC ACID.

By JOSEPH LOUIS SVIRBELY.

*From the Science Department, Margaret Morrison College, Carnegie Institute of Technology, Pittsburgh, Pennsylvania.*

*(Received May 2nd, 1935.)*

SZENT-GYÖRGYI [1928] noticed that the cortical portion of ox suprarenals turned black when immersed in neutral 0.4 % silver nitrate solution. The compound, ascorbic acid, responsible for the reduction was later isolated in crystalline form from ox suprarenals [Szent-Györgyi, 1928], paprika [Svirbely and Szent-Györgyi, 1933] and lemons [King and Waugh, 1932]. Titration with 2:6-dibromo-, or 2:6-dichloro-phenolindophenol blue indicated that the ascorbic acid content of various organs of guinea-pigs decreased when these animals were maintained on a vitamin C-free diet [Svirbely and Szent-Györgyi, 1933; Harris and Ray, 1933, 1; Bassey and King, 1933].

Many observers attempted to utilise the reduction of silver nitrate by animal organs and extracts as a criterion for the ascorbic acid content, with varying degrees of success. Marked differences were noticed in staining the cut surfaces of the suprarenals in normal and scorbutic guinea-pigs by Moore and Ray [1932], Harris and Ray [1933, 1], Siehrs and Miller [1933; 1934], and Bessey *et al.* [1934]. Gough and Zilva [1933] and Harris and Ray [1933, 2] reported that the failure of suprarenal tissue to stain deeply with silver nitrate cannot be relied on as a test for the absence of ascorbic acid or vitamin C since the adrenals of guinea-pigs which showed no evidence of scurvy on autopsy did not stain with the reagent at all. Huszak [1933] showed that a substance or substances, precipitable by lead acetate, occurred in the suprarenal medulla which prevented the reduction of silver nitrate by the suprarenal medulla and cortex. Similar inhibitory substances occurred also in lemon and paprika juice and their function was probably a stabilising of the vitamin.

In contrast to the staining by silver nitrate of the suprarenal cortex, anterior and intermediate lobes of the pituitary and ovary from various animals, the liver does not stain at all with the reagent [Gough and Zilva, 1933] nor does the suprarenal medulla [Harris and Ray, 1933, 2]. The failure of liver, suprarenal medulla or trichloroacetic acid extracts of these organs to stain with this reagent, though they contain high amounts of ascorbic acid, was difficult to explain.

Birch and Dann [1933] noticed the close similarity in occurrence of ascorbic acid and glutathione. De Caro and Giana [1934] concluded that glutathione was the substance which caused stabilisation of ascorbic acid in tissue extracts. Mawson [1935] stated that protection by tissue extracts could not wholly be explained by glutathione, cysteine, cystine or  $H_2S$  since dialysed tissue extracts retained their anti-oxidative properties in full. These properties were also present, in reduced amount, in extracts that had been boiled or precipitated with mercuric acetate.

The work of Sato and Ohata [1931] indicated that the glutathione contents of suprarenals and liver were 0.075 and 0.24 % respectively and was little changed

in scorbutic guinea-pigs, with possibly a more or less definite increase in the suprarenals. Based on the above percentages, the glutathione content of liver was 2.4 mg./g. and of suprarenals 0.75 mg./g.

The high concentration of glutathione in liver and suprarenals suggested that the failure of the silver nitrate reduction might be connected with the relative amounts of glutathione and ascorbic acid actually present in the tissues. The object of this paper is to present experimental work in testing this relationship.

#### EXPERIMENTAL.

##### *Reduction of aqueous solutions of ascorbic acid by silver nitrate in the presence of glutathione and cystine.*

Preliminary work indicated that glutathione<sup>1</sup> was precipitated by normal lead acetate, mercuric acetate and silver nitrate, but that the precipitate dissolved readily in slight excess of the reagent added. Addition of ammonium hydroxide to the clear solution obtained by adding excess of lead acetate to glutathione caused a precipitate to form at about the same  $p_{H}$  range as that in which ascorbic acid is precipitated under similar conditions. Cystine was precipitated by mercuric but not by lead acetate.

The reduction of ascorbic acid alone by silver nitrate was estimated directly in test-tubes. The rapidity and character of the precipitation depended to a great extent on the acidity or alkalinity of the reagent. An immediate production of black, finely divided particles of silver was obtained when 1 ml. of slightly ammoniacal 5 or 0.5 % silver nitrate was added to 0.015 mg. ascorbic acid. Quantities as low as 0.003 mg. ascorbic acid could thus be detected. With neutral silver nitrate of like concentrations, the particles obtained by the reduction were of larger size and had a silvery sheen. The reduction took longer and was not as sensitive as before. Slightly acid silver nitrate ( $p_{H}$  about 3) gave no marked reduction in 15 minutes with 0.15 mg. ascorbic acid although 0.3 mg. gave a gradual reduction to silvery particles.

The concentration and alkalinity or acidity of silver nitrate were very important factors when mixed solutions of ascorbic acid and glutathione were considered. It made no difference whether or not glutathione and silver nitrate were first added, followed by ascorbic acid or ascorbic acid and glutathione and then silver nitrate. Excess silver nitrate had to be present since it seemed to form a stable salt or complex with the glutathione very readily, and the excess of silver nitrate was then reduced by the ascorbic acid. Care must be taken to see that the silver nitrate is not too ammoniacal as otherwise irregular results are obtained. Sufficient ammonium hydroxide is added just to dissolve the precipitate first obtained with silver nitrate.

The results of a series of tests are given in Table I.

With approximately equal amounts of ascorbic acid and glutathione, the gradual reduction with silver nitrate was not at all comparable with the immediate reduction obtained by using ascorbic acid alone. The depth and shade of the opalescent solutions in the above concentrations depend on the relative amounts of glutathione and ascorbic acid.

Addition of 1 ml. of 0.5 % ammoniacal silver nitrate to mixtures of 0.3 mg. cystine and 0.15 mg. ascorbic acid or 0.15 mg. cystine and 0.3–0.09 mg. ascorbic acid gave an immediate reduction to black finely divided silver with a brown

<sup>1</sup> I am greatly indebted to Dr H. L. Mason, Department of Biochemistry, Mayo Clinic, Rochester, Minn., for sending me the glutathione used in this work.

*a*, Concentrations found in mouse liver/g.

*b*, Concentrations found in ox suprarenal cortex/g.

*c*, Concentrations found in suprarenals of guinea-pigs when fed a rich green diet and then placed on a vitamin C-free diet. The ascorbic acid values represent concentrations per g. while the glutathione probably corresponds to that of 0.2 g. of suprarenals.

solution if less than 0.09 mg. ascorbic acid was used. Cystine does not interfere to the same extent as glutathione with the silver nitrate test for ascorbic acid.

Adrenaline (0.025 mg.), glycogen, lactose, gelatin or starch did not interfere in the silver nitrate test with 0.15 mg. ascorbic acid.

#### *The gold chloride test for ascorbic acid.*

Gold sols are formed immediately when 3-15 mg. ascorbic acid are added to 1 ml. of 1 % gold chloride solution in 95 ml. distilled water. The sols range from purplish red to deep blood-red in colour according to the amount of ascorbic acid added. On heating no further change in colour occurs. As ordinarily prepared by the sodium citrate or formaldehyde method, the solutions must be heated for several minutes before reduction occurs.

If different concentrations of ascorbic acid are added to 1 ml. of dilute gold chloride (1 ml. 1 % gold chloride in 98 ml. H<sub>2</sub>O), the limit of sensitivity is 0.045 mg. ascorbic acid as compared with 0.015 mg. with ammoniacal silver nitrate.

Addition of glutathione to gold chloride causes the yellow colour to disappear, indicating the formation of a salt or stable complex. A turbid white solution results when excess glutathione is added. Cystine and adrenaline cause no noticeable change in the colour of the gold chloride.

No sol formation results in 15–60 minutes when 1 ml. of diluted gold chloride is added to mixtures of 0.15 mg. glutathione with 0.3–0.015 mg. ascorbic acid. Cystine gives similar results. Apparently the glutathione and cystine form stable salts or complexes with the small quantity of gold chloride present and prevent reduction by ascorbic acid.

*The silver nitrate test for liver extracts.*

The mercuric acetate treatment of Emmerie and Van Eekelen [1934] and the lead acetate method of Huszak [1933] were employed to remove the greater portion of interfering substances before the silver nitrate test was tried.

Young mice, about two months old, were etherised and their livers removed, minced with sand and extracted with three times their weight of 10 % trichloroacetic acid. Calcium carbonate was added to remove any excess acid. The yellow solution gave a strong nitroprusside reaction for glutathione and a yellow-brown precipitate with 5 % ammoniacal silver nitrate. The solution was divided into two fractions—one part was treated with normal lead acetate and the other with mercuric acetate. The amount of reagent necessary to give maximum precipitation was first determined on a small sample and excess of the reagent carefully avoided. After filtration,  $H_2S$  was passed into the colourless turbid solution to remove the mercury and lead. The sulphides were filtered off and the clear solution was allowed to stand for one hour, saturated with the gas. The gas was then removed by distillation *in vacuo* for half an hour, the cold distilling flask being immersed in warm water to facilitate concentration and removal of  $H_2S$ . The resulting concentrated solution did not react with lead acetate, copper sulphate or mercuric acetate, indicating absence of  $H_2S$ . It gave no nitroprusside test. Addition of 5 % ammoniacal silver nitrate solution gave an immediate black reduction with the fraction treated with mercuric acetate and a reddish brown reduction with the fraction treated with lead acetate. Acidic 5 % silver nitrate gave no immediate reduction though several hours later a slight reduction had occurred. Trichloroacetic acid gives a white precipitate with silver nitrate.

DISCUSSION.

The marked interference of glutathione with the silver nitrate test for ascorbic acid explains to a great extent the differences reported by many investigators who attempted to utilise this reduction as a criterion for the presence of ascorbic acid in any organ or tissue extract. The observations of Siehrs and Miller [1933; 1934] who pointed out that the intensity of the reduction in the suprarenals decreased 24 hours after guinea-pigs were taken off a rich green diet and placed on a vitamin C-free diet agrees with the results in Table I. The colour ranged from black to dark brown on the first day to a reddish orange on the sixth day when it reached the minimum. Since colour gradations depend to a large extent on the relative amounts of glutathione and ascorbic acid associated with one another as well as on the  $p_H$  of the silver nitrate, this test must be used in a qualitative rather than a quantitative sense. Likewise a failure of the test does not indicate that there is no ascorbic acid present in the organ, since the ascorbic acid content, though sufficient to ensure absence of scurvy, may be too low in comparison with the glutathione content to give a positive reaction. The test is not as definite as titration with dichloro- or dibromo-phenolindophenol blue in an acid medium.

SUMMARY.

1. The silver nitrate test for ascorbic acid depends on the relative amounts of glutathione and ascorbic acid present in an organ or extract.
2. The precautions required in order to demonstrate the silver nitrate test in liver extracts are described.
3. A method for preparing gold sols with ascorbic acid in the absence of heat is discussed.

I wish to thank Dr L. J. Harris, Dunn Nutritional Laboratory, for reading the proof and for valuable suggestions.

# CLXXXVII. THE IDENTIFICATION OF LINOLEIC AND LINOLENIC ACIDS.

BY THOMAS GEORGE GREEN AND THOMAS PERCY HILDITCH.

*From the Department of Industrial Chemistry, University of Liverpool.*

*(Received May 8th, 1935.)*

THE characterisation of linoleic and linolenic acids by oxidation respectively to tetra- and hexa-hydroxystearic acids is at present less satisfactory than that of oleic acid as dihydroxystearic acid. We have recently examined a number of reactions of these acids and their esters in the hope of finding more conclusive means of identifying them in natural fats. The results obtained afford a more quantitative comparison of different oxidation processes and products than was available hitherto, but we have not succeeded in obtaining good yields of crystalline derivatives, suitable for precise quantitative recognition of either the di- or the tri-ethenoid acid.

It should be emphasised at the outset that linoleic and linolenic acids can both only be obtained in a relatively pure condition by separating them in the form of crystalline tetra- or hexa-bromo-addition compounds and then debrominating the latter. Further, when either of the natural acids is treated with bromine, less than half is obtained as an insoluble crystalline bromo-addition product; moreover the acids regenerated from the latter, when again treated with bromine, again give less than 50 % yields of the crystalline bromo-addition products<sup>1</sup>. Thus Rollett [1909] showed that debromination of the crystalline tetrabromostearic acid (M.P. 114°, insoluble in light petroleum) from linoleic acid gave an "α"-linoleic acid which, on being treated in light petroleum with bromine, yielded the insoluble tetrabromostearic acid in an amount corresponding to not more than 43 % of the "α"-linoleic acid; the remaining product was a soluble tetrabromostearic acid, liquid at the ordinary temperature. Linolenic acid was found to exhibit similar behaviour, the hexabromostearic acids produced by addition of bromine differing in this case in their solubilities in ethyl ether.

Tetra- or hexa-hydroxystearic acids have usually been respectively obtained from linoleic or linolenic acids by the action of cold aqueous solutions of potassium permanganate. Hazura [1887] oxidised the "liquid" (unsaturated) acids of sunflower oil in this manner and obtained two tetrahydroxystearic acids, M.P. respectively 160–162° and 173–175°, in amounts apparently corresponding with about 24 and 7 % of the theoretical yield. Rollett [1909], employing regenerated "α"-linoleic acid, similarly obtained about 33 % of the theoretical yield of crude tetrahydroxystearic acids, apparently mainly the form of M.P. 173°. Nicolet and Cox [1922] record a yield of 54 % of the weight of "α"-linoleic acid taken (*i.e.* 43 % of theory) in the form of a mixture of tetrahydroxystearic acids, which melted at 162–168° and was resolved, after a long process of crystallisation from water (containing a trace of hydrochloric acid) into the two acids,

<sup>1</sup> The acids regenerated from the insoluble bromostearic acids have usually been termed "α"-linoleic or "α"-linolenic acids, whilst those from the soluble bromo-addition products are referred to as "β"-acids. This nomenclature, which has no configurational meaning, will be retained for convenience in the present paper.

M.P. 153° and 170°. Other workers have described tetrahydroxystearic acids melting over the range 152–177°; the two isomeric tetrahydroxystearic acids produced by alkaline permanganate oxidation of “ $\alpha$ ”-linoleic acid are generally accepted to be: (a) an acid (“ $\alpha$ -sativic acid”), M.P. 154–157°, moderately soluble in hot and sparingly in cold water, crystallisable from alcohol or ethyl acetate, and (b) an acid (“ $\beta$ -sativic acid”), M.P. 171–173°, slightly soluble in hot water, very sparingly soluble in hot ethyl acetate and crystallisable from acetic acid or from a somewhat large volume of ethyl acetate.

Nicolet and Cox [1922] also observed that, on addition of hypochlorous or hypobromous acid to “ $\alpha$ ”-linoleic acid, dichloro-(bromo)-dihydroxystearic acids were produced smoothly and could be converted into (impure) oily tetra-acetoxystearic acids (85 % yield). The latter, on hydrolysis, gave small amounts of two other isomeric crystalline tetrahydroxystearic acids (yield only 14 %), which melted at 144.5° and 135°; the acids of M.P. 153° and 170° were not obtained by this procedure. The acid of M.P. 144° was also obtained by Smith and Chibnall [1932] when they oxidised linoleic acid with hydrogen peroxide and acetic acid.

In the case of the triethenoid linolenic acid, Hazura [1887; 1888] oxidised the acids from linseed oil with alkaline permanganate and obtained two hexahydroxystearic (“*isolinusic*” and “*linusic*”) acids: (a) M.P. 173–175° (yield 12–16 % of the mixed fatty acids) and (b) M.P. 203° (yield 3–4 % of the mixed fatty acids), together with the two tetrahydroxystearic acids from linoleic acid; he also records the production of the acid, M.P. 201°, from regenerated “ $\alpha$ ”-linolenic acid. Rollett [1909] similarly obtained both hexahydroxystearic acids from “ $\alpha$ ”-linolenic acid, the yield of that melting at 203° being about 6 % of the theoretical amount.

Bauer and Kutsche [1925] state that ethyl linolenate does not react with hydrogen peroxide, but that it yields an oil,  $C_{20}H_{34}O_5$ , upon treatment with perbenzoic acid, which resembles that obtained on combination with gaseous oxygen and which contains 3 added oxygen atoms per mol. of linolenic acid.

#### EXPERIMENTAL.

In the course of the present work we have submitted linoleic and linolenic acids to oxidation with alkaline permanganate solutions, with hydrogen peroxide and acetic acid, and with perbenzoic acid, and have also examined the action of Prévost's reagent (silver benzoate and iodine). An attempt (unsuccessful) was also made to convert linoleic acid into a diacetylenic derivative, corresponding with the production of stearolic from oleic acid. Safflower seed oil, which contains a high proportion of linoleic acid unaccompanied by linolenic acid, and of which we had a convenient supply, was used as the chief source of linoleic acid, whilst linolenic acid was obtained from linseed oil. The regenerated “ $\alpha$ ”-forms of the two acids were employed in many cases, but we supplemented these experiments by others upon the mixed acids from the respective oils. In the case of linoleic acid, we also examined the behaviour of the regenerated “ $\beta$ ”-acid obtained from the petroleum-soluble bromination products and that of “ $\alpha$ ”-linoleic acid which had been submitted to isomerisation by oxides of nitrogen. Comparison of the results from the oxidation of the “ $\alpha$ ”-acids with those from the oxidation of the mixed fatty acids without bromination has led us to consider that the linoleic and/or linolenic acid of the original seed-fats very probably each exists in only one form, and that mixtures of hydroxy- or bromo-derivatives are produced in consequence of isomeric changes which accompany oxidation or bromination.

### LINOLEIC ACID.

" $\alpha$ "-Linoleic acid. Methyl " $\alpha$ "-linoleate (i.v. 164.3) was prepared by debromination (with zinc and methyl alcoholic hydrogen chloride) of the tetrabromostearic acid (M.P. 114°) obtained by addition of the theoretical amount of bromine to a solution of the mixed fatty acids of safflower seed oil in light petroleum (B.P. 80–100°) at 0°. " $\alpha$ "-Linoleic acid was subsequently prepared as required from the distilled methyl ester.

" $\beta$ "-Linoleic acid. " $\alpha$ "-Linoleic acid was brominated at 0° in light petroleum (B.P. 40–60°); after filtration of the crystalline tetrabromostearic acid, the solution was washed with sodium thiosulphate solution and the petroleum then removed. The residual oil (Br found: 50.5 %;  $C_{18}H_{32}O_2Br_4$  requires 53.3 %) was debrominated as above and finally yielded " $\beta$ "-linoleic acid (i.v. 133.1, Br 2.1 %). It is to be noted that, although the acid contained but little bromine, the i.v. was very low<sup>1</sup> (linoleic acid, i.v. 181.4); this may well indicate that some of the petroleum-soluble products of bromination have undergone some further change during debromination. (In the debromination of the crystalline bromo-acid, it has been definitely shown [Rollett, 1909; Hilditch and Vidyarthi, 1929] that the ethenoid bonds reappear in their original positions.)

#### *Oxidation with alkaline permanganate solutions.*

We have employed the conditions of oxidation given by Lapworth and Mottram [1925] in the case of oleic acid, as well as those described by Hazura [1887] for linoleic and linolenic acids. The first-named authors advise the use of extremely dilute solutions, which minimises further oxidation of the hydroxystearic acids. This advantage is somewhat discounted, in the cases of linoleic and linolenic acids, by the solubility in water of some of the oxidation products and we found difficulty in recovering all the tetrahydroxystearic acids (especially that of M.P. 155°) from the large volume of water present after oxidations by the Lapworth and Mottram method.

- ✓ (i) " $\alpha$ "-Linoleic acid (*modified Hazura process*). Potassium permanganate (5 g.) in ice-cold water (200 ml.) was added to a solution of the acid (4.8 g.) and potassium hydroxide (2.8 g.) in water (300 ml.) at 0°. After standing at 0° for 24 hours, the solution was decolorised with  $SO_2$  and made acid with concentrated HCl (150 ml.). The solid tetrahydroxystearic acids were filtered off and separated by fractional crystallisation from ethyl acetate (M.P. 173°, 1.3 g.; M.P. 155°, 2.6 g.). The aqueous filtrates were evaporated to dryness and extracted with hot alcohol, which removed a certain amount (1.1 g.) of viscous material from which however no further crystalline products could be extracted.
- ✓ (ii) " $\alpha$ "-Linoleic acid (*Lapworth and Mottram process*). Potassium permanganate (8 g.) in ice-cold water (400 ml.) was added to a solution of the acid (4.8 g.) and sodium hydroxide (4.8 g.) in water (2.5 litres) at 0°. After standing for 5–10 minutes, the solution was decolorised, concentrated HCl (150 ml.) added, and the tetrahydroxystearic acids filtered and separated as above (M.P. 173°, 0.9 g.; M.P. 155°, 1.4 g.; from the ethyl acetate mother-liquors 0.4 g. of material which melted indefinitely at about 128° was recovered. This appeared to consist of the acid, M.P. 155°, admixed with some azelaic or suberic acid).
- ✓ (iii) *Mixed fatty acids of safflower oil (modified Hazura process)*. The mixed acids include about 60 % of linoleic and about 25 % of oleic acid [cf. Jamieson and Gertler, 1929]. The mixed acids (4.8 g.) were dissolved with potassium hydroxide (2.8 g.) in water (300 ml.) and mixed at 0° with a solution of potassium

<sup>1</sup> Rollett [1909] records i.v. 159.5 for " $\beta$ "-linoleic acid.

permanganate (3.7 g.) in water (200 ml.). After standing at 0° for 24 hours, the products were isolated as in (i), and were found to consist of:

- (a) 0.67 g. tetrahydroxystearic acid, M.P. 172°.
- (b) 0.75 g. tetrahydroxystearic acid, M.P. 151–153°.
- (c) 0.24 g. M.P. 130–135° (impure dihydroxystearic acid).

The yields of the tetrahydroxystearic acids M.P. 172° and 151–153° correspond respectively with about 18.5 and 20 % of the theoretical, calculated on 60 % of linoleic acid in the mixed safflower fatty acids. The reduced yield of dihydroxystearic acid from oleic acid, when a mixture of oleic and linoleic acids is oxidised by aqueous alkaline permanganate, was noted by Lapworth and Mottram [1925]. It is important to bear in mind this mutual influence of one unsaturated acid upon another, if the alkaline permanganate oxidation procedure is to be employed as an analytical method for the characterisation of oleic, linoleic or linolenic acid.

(iv) Freshly-distilled methyl “ $\alpha$ ”-linoleate was shaken with mercury (0.2 g.) and nitric acid (sp. gr. 1.4, 0.5 ml.) in a stoppered bottle at room temperature for one hour in order to effect geometrical isomerisation of the ethenoid linkages [Griffiths and Hilditch, 1932]. The product was washed free from nitric acid and hydrolysed. The acids obtained (4.8 g., i.v. 137.5) were oxidised by the Lapworth and Mottram procedure, when there were finally obtained 0.35 g. (M.P. 173°) and 0.6 g. (M.P. 155°).

(v) “ $\beta$ ”-Linoleic acid (3.0 g.) was oxidised by the modified Hazura procedure, but only 0.10 and 0.07 g. of the crystalline acids M.P. respectively 173° and 155° were recovered. The main product (2.7 g.) was recovered by extraction with ether of the aqueous acid oxidation products as a mixture of oily acids (i.v. 13.7, mean equiv. wt. 76). On long standing in a vacuum desiccator the oil deposited a trace of crystalline acid which appeared to be impure suberic acid. The low equivalent of the main product indicates of course that a considerable amount of the “ $\beta$ ”-linoleic acid had undergone disruptive oxidation into short-chain acids.

The main results of the above experiments may be given in tabular form: in each case 4.8 g. of linoleic acid were oxidised and the weights and yields (% of theory) of the acids, M.P. 155° and 173°, which were obtained are shown.

Acid oxidised	Conditions of oxidation	Tetrahydroxystearic acids			
		M.P. 155°		M.P. 173°	
		g.	Yield %	g.	Yield %
Mixed safflower acids (ca. 60 % linoleic)	Hazura	0.75	20	0.7	18
“ $\alpha$ ”-Linoleic	Hazura	2.6	43	1.3	22
“ $\alpha$ ”-Linoleic	Lapworth and Mottram	1.4	23	0.9	15
“ $\alpha$ ”-Linoleic, after “elaidini- sation” with oxides of nitrogen	Lapworth and Mottram	0.6	10	0.35	6
“ $\beta$ ”-Linoleic	Hazura	0.1	2	0.15	3

The yields of the two tetrahydroxystearic acids in our experiment with “ $\alpha$ ”-linoleic acid by the Hazura method (in all 65 % of theory) are higher than previously recorded and are not, if readily reproducible, unsatisfactory as a method of identification. In the other two cases quoted, we obtained combined

yields for the two acids of 38 % of theory, a figure intermediate between those of Nicolet and Cox (43 %), Rollett (33 %) and Hazura (31 %). We believe that much of the observed variation in yield is to be ascribed to the difficult recovery and separation of the products of the oxidation. In particular, we feel that the quantitative recovery of the acid of m.p. 155°, because of its appreciable solubility in cold water and of the relatively large volumes of water necessarily present, is bound to be uncertain. In some of our experiments especial attention was paid to this feature and the aqueous solutions were considerably reduced in bulk by evaporation, a procedure which adds greatly to the length of time consumed in the operations but which probably accounts for the high yield of this acid obtained in the instance recorded.

The most significant point brought out in the table above is that the linoleic acid present in the mixed acids of safflower oil appears to have given yields of the two tetrahydroxystearic acids of much the same order as those usually observed in the case of " $\alpha$ "-linoleic acid. In conjunction with the evidence obtained in the oxidation of " $\beta$ "-linoleic acid (*cf.* below), this seems fairly conclusive evidence that the natural linoleic acid in the seed fat behaves, so far as the alkaline permanganate oxidation is concerned, as if it were the " $\alpha$ "-acid.

The small yields of the acids, m.p. 155° and 173°, from the oxidation of the " $\alpha$ "-linoleic acid after its treatment with the "elaidin" reagent show, if indeed proof be required, that the proportions of these acids produced are dependent on the geometrically isomeric forms of  $\Delta^{9,10,12,13}$ -octadecadienoic acid which may be present. In this experiment, in addition to the acids shown in the table, a very small amount (0.1 g.) of a third tetrahydroxystearic acid, m.p. 140–141° (the melting point of which was depressed on admixture with the acid of m.p. 146°, *v. infra*) was also produced.

The oxidation of " $\beta$ "-linoleic acid with alkaline permanganate (which, curiously, does not seem to have been investigated by the earlier workers) gave mainly an oil (i.v. 13.7, mean equiv. wt. 76) from which a very small amount of an acid (apparently suberic acid) was isolated. The general properties of this substance indicate that the " $\beta$ "-acid had undergone profound disruptive oxidation under the conditions of the Hazura process. " $\beta$ "-Linoleic acid yields extremely small proportions of the two tetrahydroxystearic acids, m.p. 155° and 172°, less in fact than the "elaidinised" or isomerised " $\alpha$ "-acid. If therefore natural linoleic acid (*e.g.* in seed fats) were indeed a mixture of isomeric " $\alpha$ "- and " $\beta$ "-forms, the yields of these two acids would be quite uncertain criteria of the presence of the acid. We feel however that all the properties of the " $\beta$ "-acid suggest that it may be a somewhat complex mixture of several transposition products resulting from the action of bromine on the natural acid, and that the latter, although it gives rise (like the " $\alpha$ "-acid) to two forms of tetrahydroxystearic acid, may well be a stereochemical individual, probably, in view of the independent work of Nicolet and Cox [1922] and of Suzuki *et al.* [1931; 1932], the *cis-cis*- $\Delta^{9,10,12,13}$ -octadecadienoic acid. This view is certainly reinforced by the similarity in yields of the two tetrahydroxystearic acids, m.p. 155° and 172°, from natural and from " $\alpha$ "-linoleic acid.

#### *Oxidation with hydrogen peroxide and acetic acid.*

(i) Methyl " $\alpha$ "-linoleate (10 g.) was dissolved in glacial acetic acid (100 ml.); perhydrol (35 %  $H_2O_2$ , 10 ml.) was added at 0° and the solution kept at this temperature for 2 days, during which 30 ml. more of perhydrol were added (with 100 ml. of acetic acid to maintain complete solution of the ester). The solution was kept at 0° for a further 7 days. It was then poured into excess

of 7 % aqueous ammonia solution and the oxidation products were removed by extraction with ether and converted into the free acids as described by Hilditch and Lea [1928]. The ether solution of the free acids deposited a solid compound (1.8 g.) which, after recrystallisation from ethyl acetate, melted at 146°. (Found: C, 61.6; H, 9.9 %.  $C_{18}H_{36}O_8$  requires C, 62.1; H, 10.3 %.) This tetrahydroxystearic acid was distinct from that melting at 155° (a mixture of the two acids melted indefinitely between 141° and 148°).

The residue (7.4 g.) from the ether solution was an oil (i.v. 6.9) which, after standing for some weeks, deposited a small quantity (0.3 g.) of a solid acid which melted, after crystallisation from ethyl acetate, at 126°. (Found: C, 62.7; H, 10.3 %.) No further crystalline products were obtained from this oil, which formed the greater part of the products of oxidation.

The yields of the two isomeric tetrahydroxystearic acids, m.p. 146° and 126°, were respectively about 14 and 2 % of the theoretical.

(ii) Methyl "α"-linoleate (10 g.) was similarly oxidised in acetic acid solution (100 ml.) with perhydrol (40 ml., added in two portions) at 70–80° for 10 hours. The product was worked up as in (i), and a small quantity (0.4 g.) of the acid, m.p. 146°, separated from the ether solution of the recovered acids. The remainder (5.0 g.) of the product was an oil (i.v. 14.1) from which boiling water removed a very small quantity of a solid acid; this, on crystallisation from benzene, melted at 95° and appeared to be azelaic acid; no other crystalline acids could be obtained from the oil. The loss of material (nearly 5 g.) in this experiment is noteworthy, and suggests considerable formation of water-soluble acids of low molecular weight: it was also observed that the alcoholic alkaline solution became very dark in colour during the hydrolysis of the oxidised esters.

(iii) The methyl esters (10 g.) of the mixed fatty acids from safflower seed oil were treated in glacial acetic acid (150 ml.) with perhydrol (30 ml.) at 0° for a week under the conditions described in the preceding experiment (i). The products finally isolated included:

0.37 g. tetrahydroxystearic acid, m.p. 146° (equivalent to about 5 % of the linoleic acid present; m.p. unchanged on admixture with the corresponding acid, m.p. 146°, from experiment (i));

0.1 g. tetrahydroxystearic acid, m.p. 119–121°, which was apparently an impure specimen of that obtained in experiment (i) (mixed m.p. 121–125°). This corresponds with about 1 % of the linoleic acid present;

1.1 g. 9:10-dihydroxystearic acid, m.p. 92° (m.p. 93° when mixed with pure 9:10-dihydroxystearic acid of m.p. 95°);

5.9 g. of viscid, indefinite products of oxidation (i.v. 16.3).

(iv) "β"-Linoleic acid (3.9 g., i.v. 133) was similarly oxidised in glacial acetic acid (60 ml.) with perhydrol (12 ml.) at 0° for a week. Almost the whole of the products recovered was in the form of a very viscous, gum-like material which showed the typical reactions of an organic peroxide (4.0 g., i.v. 11.9. On heating under vacuum at 100° for 1 hour, evolution of gas took place and the i.v. of the substance increased to 14.3). A very small amount (0.03 g.) of tetrahydroxystearic acid, m.p. 141–144°, was the only other product isolated.

It seems certain that the tetrahydroxystearic acid, m.p. 146° (which was similarly obtained from linoleic acid by Smith and Chibnall [1932]) is the same compound as that described by Nicolet and Cox [1922]; but the other isomeric acid, m.p. 126°, does not appear to be the same as the acid of m.p. 135° obtained by the latter authors.

Towards hydrogen peroxide (or peracetic acid), as well as towards alkaline permanganate therefore the behaviour of the natural linoleic acid differs ma-

terially from that of either oleic or elaidic acid. The monoethenoid acids (especially elaidic) are readily converted by hydrogen peroxide and acetic acid into one or other of the isomeric 9:10-dihydroxystearic acids; moreover, in the case of oleic acid the dihydroxy-acid produced is that melting at 95°, whilst elaidic acid yields the other form, M.P. 132° (*i.e.* the opposite acid is produced in each case to that obtained by the use of alkaline permanganate). With linoleic acid, two new tetrahydroxystearic acids are produced, in very small yields, but neither has apparently any simple relationship to those obtained in the alkaline permanganate oxidation. This is illustrated by the fact that alkaline permanganate oxidation of methyl "α"-linoleate which had been "elaidinised" did not furnish either of the acids, M.P. 146° or 126°. (The possible stereochemical relationships of isomeric 9:10:12:13-tetrahydroxystearic acids have been discussed by Nicolet and Cox [1922].)

Linoleic acid and esters are largely converted at 0° by hydrogen peroxide into viscous products of an organic peroxide or "linoxyn"-like character, a behaviour which is exhibited to a considerably smaller extent by monoethenoid acids or esters [Hilditch and Lea, 1928]; at higher temperatures (70°) breakdown of the carbon chain evidently becomes an important feature of the process. As a practical method for characterisation of linoleic acid, the hydrogen peroxide-acetic acid oxidation is seen to be definitely inferior to oxidation with alkaline permanganate.

#### *Oxidation with perbenzoic acid.*

Perbenzoic acid (9.5 g., prepared by the method of Hibbert and Burt [1925] in 190 ml. chloroform) was left with methyl "α"-linoleate at 0° in the dark for 3 days. From the cold alcoholic alkaline solution employed to hydrolyse the resulting esters [*cf.* Böeseken, 1926; Steger and van Loon, 1927], there separated a crystalline potassium salt, the acid (2.6 g.) from which melted, after crystallisation from 70 % alcohol, at 79°. (Found: C, 69.0; H, 10.8 %.  $C_{18}H_{32}O_4$  requires C, 69.2; H, 10.3 %.) This corresponds with a dioxidostearic acid, but the compound could not be converted into a crystalline tetrahydroxystearic acid by either of the methods by which the above investigators have effected the transformation of mono-oxidostearic acids into 9:10-dihydroxystearic acids. The main product of the reaction was an oil (5.4 g., obtained from the products of cold alkaline hydrolysis of the esters after separation of the above-mentioned crystalline potassium salt). This deposited some solid on keeping, but attempts to separate and purify the latter were unsuccessful. The oil, originally mobile and pale in colour, darkened and became viscous on heating at 100° in a vacuum.

The yield of the dioxidostearic acid (about 25 % of the theoretical) was moderately satisfactory, at all events by comparison with those from most of the other processes discussed in the present paper.

#### *Oxidation by means of silver benzoate and iodine in benzene.*

The use of this reagent for the conversion of aliphatic ethenoid groups into diglycols has recently been proposed by Prévost [1933]. Since it does not seem to have been applied hitherto to the higher unsaturated fatty acids, we examined its action on the monoethenoid compounds, methyl oleate and elaidic acid, before employing it in the case of linoleic acid.

*Methyl oleate.* Dry silver benzoate (15.5 g.) was added to a solution of methyl oleate (10 g.) in benzene (200 ml.). To the boiling solution there was added a solution of iodine (8.7 g.) in benzene (50 ml.). After refluxing for 3 hours, silver iodide was removed by filtration, and the residue (13 g., *i.v.* 5.5), after removal

of the benzene, was hydrolysed by *N*/2 alcoholic KOH (250 ml.). The ether solution of the acids so obtained deposited a solid acid (4.1 g.), which, after recrystallisation from ethyl acetate, melted at 130° (unchanged on admixture with 9:10-dihydroxystearic acid, M.P. 131°). The acids which remained in solution in the ether were freed from benzoic acid and were mainly liquid. 1.2 g. of a solid acid were separated from them however which, on purification, melted at 95° (no depression in M.P. when mixed with 9:10-dihydroxystearic acid, M.P. 95°); the remainder of the material (3.8 g.) remained in the form of an oil.

*Elaidic acid* (10 g.) were treated in a manner similar to the above and finally yielded about 5.8 g. of a solid acid, which, on crystallisation, was found to consist entirely of the 9:10-dihydroxystearic acid of M.P. 95° (M.P. observed, 93–94°, unchanged on admixture with the pure acid). The isomeric dihydroxystearic acid (M.P. 131°) was not detected; the remainder of the product was an oil (4.0 g.).

It thus appears that, with the simple monoethylenic acids, Prévost's reagent leads to the production in about 50 % yield of a dihydroxystearic acid, the remainder being an oil of indefinite character; for the most part, also, the dihydroxystearic acid produced is the same form as that obtained by oxidation of the original ethylenic acid with alkaline permanganate.

When methyl "α"-linoleate was submitted to this process, however, it was almost wholly converted into a gummy material, from which extremely small amounts of the two tetrahydroxystearic acids, which result from the alkaline permanganate oxidation, were recovered. From 10 g. of methyl "α"-linoleate there was obtained a dark-coloured gum (11 g., I.V. 46.7), together with 0.3 g. tetrahydroxystearic acid, M.P. 153° and 0.1 g. (M.P. 168°) of an impure specimen of the isomeric acid of M.P. 173°.

#### *Action of alcoholic alkali upon tetrabromostearic acid.*

We re-examined the action (which has been studied by other workers) of ethyl alcoholic potash at different concentrations and temperatures upon the tetrabromostearic acid, M.P. 114°, derived from linoleic acid, but in no case, nor by the use of silver oxide, were we able to obtain any tetrahydroxystearic acids. Removal of hydrogen bromide, with the production of ethylenic acids which usually also retain one or more bromine atoms, appeared to be the predominant action in all cases [cf. Albitski, 1899; Suzuki and Maruyama, 1931; 1932].

We also heated tetrabromostearic acid with concentrated amyl alcoholic KOH in the hope of producing a diacetylenic analogue of stearolic acid (from dibromostearic acid, cf. Overbeck [1866]). Tetrabromostearic acid (M.P. 114°, 20 g.) was refluxed with a solution of sodium hydroxide (14.4 g.) in amyl alcohol (60 ml.) for 4 hours. After removal of the amyl alcohol by distillation in steam, 8.9 g. of oily acids (I.V. 135.0) were recovered. The lithium salts of these acids were completely soluble in 95 % acetone, whilst over 90 % of their lead salts were soluble in 95 % alcohol. It seems therefore that little or no diacetylenic acid had been produced, and that regeneration of octadecadienoic acids had mainly taken place.

#### LINOLENIC ACID.

##### *Oxidations with alkaline permanganate solutions.*

By oxidation of either "α"-linolenic acid or the mixed acids from linseed oil with alkaline permanganate we obtained the two hexahydroxystearic acids (M.P. 203° and 169°) in small yields of the order of those recorded by Hazura

[1888] and by Rollett [1909]. Attempts to increase the yields of these acids were uniformly unsuccessful.

(i) The aqueous soap solution (150 ml.) obtained from the hydrolysis of ethyl " $\alpha$ "-linolenate (4.7 g.) was mixed at 0° with a solution of potassium permanganate (12 g.) in water (400 ml.) and kept at 0° for a day. After decoloration and acidification with sulphuric acid a small amount of solid (0.2 g.) separated which, after crystallisation from alcohol, melted at 203°. (Found: C, 56.6; H, 9.8 %.  $C_{18}H_{36}O_8$  requires C, 56.9; H, 9.5 %.) The aqueous filtrate was concentrated, after neutralising, to about 150 ml. and again made acid and filtered whilst hot, when 0.8 g. of acid, m.p. 180–188° (indef.) was separated; the filtrate, on cooling at 0° overnight, deposited 0.6 g. of acid, m.p. 174°. These two acid fractions were separately crystallised several times from alcohol, and eventually there were obtained in all (a) 0.3 g. more of the acid, m.p. 203°, and (b) 0.7 g. of an acid which finally melted at 166°. (Found: C, 57.2; H, 9.7 %.) Thus, in all, from 4.2 g. of linolenic acid there were isolated 0.5 g. of hexahydroxystearic acid, m.p. 203°, and 0.7 g. of hexahydroxystearic acid, m.p. 166°, representing together a yield of about 18 % of the theoretical.

(ii) The mixed fatty acids (50 g.) of linseed oil were dissolved in water (1 litre) with potassium hydroxide (12 g.) and mixed at 0° with a solution of potassium permanganate (50 g.) in water (2 litres) [Hazura and Friedreich, 1887]. After 24 hours, the solution was decolorised with  $SO_2$  and made acid with dilute  $H_2SO_4$ , and the precipitated acids (which consisted mainly of hexahydroxystearic acid, m.p. 203° and the two tetrahydroxystearic acids, m.p. 155° and 173°) were filtered. These were boiled with water, when most of the hexahydroxystearic acid and of the tetrahydroxystearic acid, m.p. 155°, dissolved. The insoluble portion was recrystallised from alcohol and was found to be tetrahydroxystearic acid (0.2 g., m.p. 173°) containing a little hexahydroxystearic acid. (Found: C, 61.2; H, 10.1 %.)

When the water-soluble portion was treated with ethyl acetate, the hexahydroxystearic acid remained undissolved and was further purified by crystallisation from ethyl alcohol (1.1 g., m.p. 203°); the more soluble portion was twice recrystallised from ethyl acetate (0.1 g., m.p. 150°).

The original acid filtrates from the oxidation were neutralised and concentrated to 400 ml.; after again adding sulphuric acid, an acid separated which melted at 167°. This, the main yield of hexahydroxystearic acid, was mixed with small amounts of lower-melting hexahydroxystearic acids obtained in the above separations and yielded, after two crystallisations from methyl alcohol, a product (2.5 g.) which melted at 169–170°. (Found: C, 57.1; H, 9.3 %.)

Calculated on the amounts (approx. 40 % each) of linolenic and linoleic acids present in the original mixed linseed oil acids, the yields of the four products were about 5 % of hexahydroxy-acid, m.p. 203°, 10 % of hexahydroxy-acid, m.p. 169–170°, 0.8 % of tetrahydroxy-acid, m.p. 173°, and 0.5 % of tetrahydroxy-acid, m.p. 155°, as compared with theory. It is noteworthy that the yields of the tetrahydroxystearic acids in this experiment were much lower than when linoleic acid was oxidised under similar conditions, but in absence of linolenic acid. This behaviour has an exact parallel in the analogous falling-off in the yield of 9:10-dihydroxystearic acid from oleic acid when a mixture of the latter with more than a certain maximum of linoleic acids is oxidised with alkaline permanganate.

*Oxidation with hydrogen peroxide and acetic acid.*

Ethyl " $\alpha$ "-linolenate (10 g.) was dissolved in glacial acetic acid (200 ml.) and perhydrol (60 ml.) added, the solution being kept at 0° for 10 days. The material was then worked up as described in the case of the corresponding experiment with methyl " $\alpha$ "-linoleate, but no crystalline potassium salts separated, and the product obtained (6.5 g., i.v. 39.3) was a viscous oil from which no crystalline solids could be isolated. This oil showed the characteristic properties of an organic peroxide and, when heated at 100° in a vacuum, evolved gas abundantly, its i.v. increasing to 52.8. It thus closely resembled in properties the oils obtained as by-products during the similar oxidations of methyl oleate or elaidate [Hilditch and Lea, 1928]. Approximately one-third of the original ester had disappeared, presumably in the form of free acids removed during neutralisation of the acetic acid (solvent) with aqueous ammonia: so that a considerable proportion of the ester had undergone disruptive oxidation.

*Oxidation with perbenzoic acid.*

Ethyl " $\alpha$ "-linolenate (15 g.) in chloroform (305 ml.) was mixed with perbenzoic acid (21 g.) and the solution kept at 0° for 10 days. The products (isolated as in the case of the corresponding experiment with linoleic ester) were a pale yellow oil (3.7 g., i.v. 8.3) readily soluble in ether and a thick gum (10.6 g., i.v. 3.0, equiv. wt. 319.6) which was sparingly soluble in ether but readily so in alcohol. Like the corresponding material obtained under these conditions by Bauer and Kutsche [1925], the composition of this gum appears to approximate to that of a compound  $C_{17}H_{29}(O_3)CO_2H$  (equiv. wt., calc., 326). No crystalline oxido-compounds were isolable, nor was it found possible to convert the gum into crystalline hydroxy-acids by hydrolysis with 5 % sulphuric acid dissolved in 50 % aqueous acetic acid (method of Böseken [1926]).

## SUMMARY AND DISCUSSION.

The above results may be summed up by saying that, so far as the characterisation of linoleic or linolenic acids is concerned, we have found no better method than the original process of oxidation with alkaline permanganate as proposed by Hazura, but that this procedure, at best, leads to the isolation of crystalline tetra- or hexa-hydroxystearic acids in yields which respectively correspond with only about 40 % of theory from linoleic, or 15–18 % of theory from linolenic, acid.

Of the alternative methods we have examined, the only promise was shown in the oxidation of linoleic acid by perbenzoic acid when, however, only a 25 % yield of a crystalline product resulted; with linolenic acid perbenzoic acid furnished no crystalline products. Hydrogen peroxide in acetic acid (peracetic acid) gave small yields of two other isomeric tetrahydroxystearic acids from linoleic acid, but no definite products in the case of linolenic acid. The other methods studied all led to negative results.

On the other hand, the data given in this paper (chiefly those which concern the oxidations with alkaline permanganate) lead to several definite conclusions of some importance. Firstly, we have already emphasised the similarity in yield of tetrahydroxystearic acids from the linoleic acid in a natural fat and from " $\alpha$ "-linoleic acid (prepared from the crystalline form of tetrabromostearic acid); taken in conjunction with the failure of " $\beta$ "-linoleic acid to yield any

appreciable quantity of either of the crystalline tetrahydroxystearic acids (a feature apparently not previously examined), this points strongly to the likelihood that the linoleic acid of seed-fats is confined to one geometrical form. The latter evidently undergoes isomeric change or "inversion" to some extent during bromination or oxidation.

Secondly, our results leave us unsatisfied that the so-called " $\beta$ "-linoleic acid is simply a mixture of other forms of  $\Delta^{9,10,12,13}$ -octadecadienoic acid. From the oxidation results, it appears still to contain a certain amount (perhaps 10–12 %) of the " $\alpha$ "-acid; whilst, from its low i.v. and other considerations, we are inclined to suspect that part, at least, of this product has undergone more profound alteration than the mere conversion of *cis*- into *trans*-ethenoid linkages.

We consider the behaviour of "elaidinised" " $\alpha$ "-linoleic acid to be much more significant. Here we know that the action of oxides of nitrogen is confined to effecting *cis-trans* isomerisation (except for the subsidiary production of small proportions of stable nitroso- or nitro-addition products). The isomerised acid still furnished, as would be expected from an equilibrium mixture of isomerides, a certain diminished yield of the usual tetrahydroxystearic acids, but no others (except for a minute amount of the isomeride of m.p. 146°). We regard this as evidence that some at least of the remaining three geometrical isomerides of  $\Delta^{9,10,12,13}$ -octadecadienoic acid do not yield any crystalline tetrahydroxystearic acids under the conditions of the Hazura oxidation. Inability to obtain these acids from an octadecadienoic acid therefore only proves the absence of the isomeride present in seed fats (or the " $\alpha$ "-linoleic acid), and does not exclude the presence of other forms of the  $\Delta^{9,10,12,13}$ -acid (or, of course, of other positional isomerides).

Another point which has emerged during the present study is that the isomeric tetrahydroxystearic acids obtained from linoleic acid on the one hand with alkaline permanganate and on the other hand with hydrogen peroxide in acetic acid do not bear any simple relationship to each other, whereas in the corresponding monoethenoid series (oleic and elaidic acids) there is a very definite interrelationship in this respect.

Although much of the evidence discussed in this communication is negative in tendency, it is felt desirable to place it on record for the following reasons: (a) the whole subject seemed to merit re-examination on a systematic basis in one investigation, in view of the somewhat divergent statements in the literature; (b) it was desirable to standardise, if possible, the criteria for natural linoleic (and linolenic) acids; (c) so far as the authors are concerned, the work forms an essential preliminary to the further investigation of the unsaturated  $C_{18}$ -acids of butter fat to which we return in the following paper.

# CLXXXVIII. SOME FURTHER OBSERVATIONS ON THE OCCURRENCE OF AN OCTADECADIENOIC ACID IN COW BUTTER FATS.

By THOMAS GEORGE GREEN AND THOMAS PERCY HILDITCH.

*From the Department of Industrial Chemistry, University of Liverpool.*

*(Received May 8th, 1935.)*

THE presence in cow milk fats of an octadecadienoic acid (and, especially, of ordinary linoleic acid ( $\Delta^9$ <sup>10</sup>, <sup>12</sup><sup>13</sup>-octadecadienoic acid) in the form in which it occurs in seed fats) has been for some time past a matter of discussion. Hilditch and Jones [1929] examined the acids from pure  $C_{18}$  ester fractions obtained in the course of quantitative fractional distillation of the methyl esters from the "liquid" acids of butter fat and failed to obtain any characteristic tetrahydroxystearic acid by oxidation, or any definite brominated acid (other than a trace of ether-insoluble bromo-acids which darkened without definitely melting at 170–180°). More recently Eckstein [1933] obtained small yields of crystalline bromo-addition products from the unsaturated acids of cow milk fat which however only accounted for about 0.2 % each of linoleic and linolenic acids, whilst Bosworth and Brown [1933], studying fractions obtained by the distillation of the mixed methyl esters of cow butter fat (without recourse to prior separation of the latter into mainly saturated and mainly unsaturated portions), have concluded that neither ordinary linoleic, linolenic nor stearidonic acid is present. The latter authors attribute any polyethenoid unsaturation in cow butter fat to small proportions of arachidonic acid,  $C_{20}H_{32}O_2$ , a statement which implies that diethylenic  $C_{18}$  acids (in any form) are absent. Later, Bosworth and Sisson [1934] have stated that arachidonic acid and small proportions of behenic acid are present in butter, which however contains no arachidic, linoleic or linolenic acid. On the other hand, Bosworth [1934] has examined human milk fat, using the same partial fractionation separation as that of Bosworth and Brown, and obtained ester fractions containing  $C_{18}$  unsaturated acids which gave without difficulty the tetrabromostearic acid, M.P. 113°, characteristic of ordinary linoleic acid.

The amount of arachidonic acid present in cow butter fat is insufficient however to account for the unsaturation displayed by the  $C_{18}$  ester fractions which are consistently obtained from cow butter fatty acids which have been correctly separated and submitted to the ester fractionation process [Hilditch, 1934]. The ester fractions in question invariably correspond to 15–20 % of the total butter fatty acids and possess an average unsaturation more than 10 % in excess of that of methyl oleate. If, as appears almost certain, stearidonic or linolenic acids, if not absent, are present in only minute proportions, the excess of unsaturation over that demanded by oleic acid remains to be explained. The work now recorded, which has been directed towards this end, includes an examination, by various means, of the acids in these particular ester fractions. The results of the investigation are uniformly consistent with the view that the unsaturation in question is due to the presence of an octadecadienoic acid; and,

although it has unfortunately not proved possible to isolate either the acid itself or any characteristic crystalline derivative thereof, we believe that our results point to the presence of one or more of the geometrically isomeric forms of  $\Delta^{9,10,12,13}$ -octadecadienoic acid (other than ordinary linoleic acid).

*Preparation of methyl esters of C<sub>18</sub> unsaturated acids  
from cow butter fat.*

The butter fat used in the present experiments was from a composite sample of milk from several members of the Shinfield typical herd, taken while the cows were at pasture in the early summer (June) of 1934. About 1350 g. of fat were used to provide the experimental material; this was worked up in batches of 450 g. according to our usual procedure for quantitative determination of the component acids, although a full analysis of the fat was not made in the present instance. The mixed fatty acids from each batch were distilled in steam to remove the acids of lower molecular weight, and the residual fatty acids were submitted to the usual lead salt-alcohol separation. The acids from the alcohol-soluble lead salts were converted into methyl esters and fractionally distilled in the usual way. The results of this distillation in the case of the first batch of butter fat (450 g.) are given in Table I.

Table I. *Fractionation of methyl esters of "liquid" acids  
from cow butter fat (450 g.).*

Fraction	g.	B.P.	S.E.	I.V.
L1	61.77	30-139	240.6	37.0
L2	19.30	139-143	287.2	83.4
L3	17.26	143-146	291.6	88.5
L4	17.69	146-149	293.6	93.5
L5	18.19	149-152	294.7	95.3
L6	19.39	152-157	295.6	96.8
L7	17.46	157-146	297.2	98.7
L8	10.72	146-falling	297.3	101.1
L9	11.62	Residue	346.5	111.4
	193.40			

Fractions L4, L5, L7 and L8 were mixed and redistilled (Table II).

Table II. *Refractionation of ester fractions L4, L5, L7, L8.*

Fraction	g.	B.P.	S.E.	I.V.
L'1	5.11	146-150°	—	93.6
L'2	13.14	152-155	295.0	94.2
L'3	20.23	155	296.5	97.8
L'4	6.97	155-falling	—	100.9
L'5	1.30	Residue	—	—

Of the above, L'2, L'3 and L6 were accepted as C<sub>18</sub> unsaturated ester fractions.

The other two batches of butter fat similarly yielded the following primary C<sub>18</sub> ester fractions:

	g.	S.E.	I.V.
From batch 2	108.0	295.9	96.2
From batch 3	108.0	295.8	93.5

These two fractions were united and refractionated (Table III).

Table III.

Fraction	g.	B.P.	I.V.
L" 1	19.18	138-142°	—
L" 2	52.63	142-145	88.1
L" 3	48.06	145-146	90.6
L" 4	44.02	146-158	95.5
L" 5	34.74	158-160	98.7
L" 6	9.59	Residue	—
	208.22		

Fractions 2, 3, 4 and 5 (Table III) were used in preparing concentrates of the unsaturated esters in the manner about to be described.

*Further concentration of polyethenoid acids by crystallisation of lithium salts from alcohol.*

Apart from the fact that these acids do not yield crystalline bromo-derivatives, we felt, for reasons dealt with in the preceding paper, that a chemical method of separation of any octadecadienoic acid present was undesirable. Owing to the greater solubility of linoleic salts as compared with those of oleic acid, separation by purely physical methods is not easy; but we found that by crystallising the lithium salts of the  $C_{18}$  unsaturated acids from the above ester fractions from 80 % alcohol, it was possible to increase the i.v. of the acids whose lithium salts remained in solution to about 115, representing (in a mixture of oleic and octadecadienoic acids) a concentration of 25-27 % of the latter. It was not found possible to exceed this figure, and the concentrates thus obtained were used for the remainder of the experiments.

*Crystallisation of lithium salts from 95 % acetone.* Before undertaking the lithium salt-alcohol separations however an experiment was made in order to ascertain the proportion and i.v. of the acids whose lithium salts were soluble in 95 % acetone. Lithium salts of the polyethenoid acids (stearidonic, arachidonic *etc.*) are freely soluble in this medium [Tsujiimoto, 1920; Ault and Brown, 1934].

A portion of the acids from the ester fraction L6 (Table I) (8.6 g., i.v. 101.5) was dissolved in warm acetone and neutralised with aqueous lithium hydroxide, the solvent being finally adjusted so as to contain 95 % of acetone and 5 % of water. From the lithium salts which crystallised out there were recovered 7.8 g. of fatty acids (i.v. 97.9) while the mother liquors contained lithium salts which yielded 0.6 g. of acids (i.v. 116.8). This result shows that the proportion, if any, of arachidonic or other highly unsaturated acid present in this fraction could only have been exceedingly small (arachidonic acid i.v. 334, stearidonic acid i.v. 368).

*Concentration of the polyethenoid acids by crystallisation of lithium salts from 80 % alcohol.* The method used was that of Moore [1919]. The fatty acids (*e.g.* 10 g.) were dissolved in 95 % alcohol (40 ml.) and exactly neutralised with approximately 4*N* aqueous lithium hydroxide solution, after which alcohol was added to bring the composition of the solvent to 80 % alcohol, 20 % water. The solution was then cooled to 10°, the crystallised lithium salts were filtered and washed with 80 % alcohol, and the fatty acids were recovered both from the crystallised salts and from those remaining in solution.

The acids recovered from the soluble lithium salts (in which the proportion of polyethenoid acids had been increased, owing to separation mainly of oleic acid in the insoluble salts) were submitted to the same procedure a second and even a third time, with reduction where possible in the ratio of solvent to total

lithium salts; but it was found that, when the acids from the soluble lithium salts had reached i.v. about 113, further increases in i.v. were relatively small, and could only be obtained with concurrent loss of considerable proportions of acids of mean i.v. > 100 in the deposited lithium salts. The results of the successive crystallisations undertaken are summarised in Table IV.

Table IV. *Partial concentration of polyethenoid acids by lithium salt-alcohol crystallisations.*

In Table V is a list of the more unsaturated acid fractions finally obtained, some of which we employed in the subsequent experiments.

Table V. *Final acid fractions used for further examination.*

	A	B	C	D	E	F	G	H
Wt. (g.)	5.6	11.9	15.8	15.5	11.0	14.5	14.3	9.4
i.v.	106.9	109.2	109.4	110.2	113.4	113.5	114.8	118.8

The mean mol. wt. of the acids G (i.v. 114.8) was 280.1; since lithium salts of palmitic and myristic acids are almost insoluble in 80 % alcohol, the procedure employed will have concurrently led to the removal of any traces of these acids present in the original ester fractions, and therefore the observed value for the mean mol. wt. indicates that the acids consisted wholly of members of the C<sub>18</sub> series.

*Bromo-addition products of the unsaturated C<sub>18</sub> acids.*

The acids G (i.v. 114.8, 5 g.) were dissolved in anhydrous ether (50 ml.) and cooled to -10°. Bromine (2.5 ml.) was slowly added from a burette during a period of 1 hour, the temperature being kept below -5°. After standing at -10° for 2 hours, the solution was filtered and the separated crystalline bromo-addition products were washed with ice-cold ether (50 ml.), dried at 90° for 2 hours and weighed. The ether filtrates were washed with a little aqueous sodium bisulphite, the ether was removed and the residue was dissolved in light petroleum (B.P. 40-60°, 10 ml.); on cooling the solution to 0° a small amount of solid separated and was filtered. After complete removal of the light petroleum from the mother-liquor a pale yellow oil remained.

The weights, bromine contents and M.P. of these three products are recorded in Table VI, which also shows the weights of fatty acids (and their mean i.v.) corresponding with the observed bromine contents.

Table VI. *Bromo-addition products of fatty acids G (5 g., i.v. 114.8).*

Separation	Bromo-addition products			Corresponding unsaturated acids		
	g.	% Br	M.P.	g.	%	i.v.
Insoluble in ether	0.19	65.8	Indefinite, charred at 160°	0.065	1.2	304.9
Soluble in ether, insoluble in light petroleum at 0°	0.06	64.7	165° with charring	0.02	0.4	291.1
Soluble in light petroleum at 0°	8.20	40.0	Liquid	4.92	98.4	105.9

It will be seen that, in agreement with previous observations, no indication of crystalline insoluble tetrabromostearic acid, M.P. 114°, is given by these results, the small amounts of ether- or petroleum-insoluble bromo-addition products melting indefinitely and charring at about 160° and containing about 65 % of bromine. In the light of Bosworth and Sisson's recent study [1934] of the bromo-addition products from arachidonic acid, these products might be derived from the latter; they might equally well, from the data, include a certain amount of the bromo-addition products of linolenic or stearidonic acid (% Br (theory): octabromoarachidic acid 67.8 %, octabromostearic acid 69.9 %, hexabromostearic acid 63.3 %). However this may be, the fatty acids represented by these crystalline bromo-products only form 1.6 % of the whole fraction.

The remaining 98.4 % of fatty acids yield the liquid, petroleum-soluble products, and neither the proportion nor the bromine content of these soluble products appears to have been considered by Eckstein or by Bosworth and Brown. The bromine content, as would be expected, is definitely higher than that of dibromostearic acid (36.2 %), although the calculated mean i.v. for the original mixture of acids (from the last column of Table VI) is only 109.4 as compared with 114.8 (observed); in other words, the total addition of bromine was about 4.5 % short of the theoretical, in terms of the (Wijs) i.v. determinations.

This result establishes definitely that the material, which gives rise in these acids to i.v. in excess of that of oleic acid, also yields bromo-addition products of corresponding bromine content which, to an overwhelming extent, are liquid and soluble in light petroleum at 0°.

We have found that, when linolenic acid (of linseed oil) is brominated, the ether-soluble bromo-addition products are also soluble to the extent of somewhat less than 50 % in petroleum (representing about 25 % of the total linolenic acid). If the 98.4 % of acids yielding petroleum-soluble bromo-addition products in Table VI consisted of a mixture of oleic and linolenic acids, the proportion of the latter in this fraction would have been about 9 %, that is, about 5-6 times as much as the whole of the unsaturated acids which yielded crystalline addition products containing about 65 % of bromine. It is therefore extremely unlikely that the polyethenoid acid present is linolenic acid, and correspondingly less likely that it is stearidonic or other still less saturated acid. The only alternative is of course an octadecadienoic acid.

The composition of the unsaturated acids (G) of i.v. 114.8 indicated by these bromo-addition products is thus (in round numbers): oleic acid 75 %, octadecadienoic acids 23.5 %, tri- and/or tetra-ethenoid C<sub>18</sub> acids 1.5 %.

*Oxidation of the methyl esters of the C<sub>18</sub>-unsaturated acids by potassium permanganate in acetone.*

When ordinary methyl linoleate or methyl oleate is oxidised by potassium permanganate in acetone the products are methyl hydrogen azeläate and, respectively, *n*-hexanoic or *n*-nonanoic acid [Armstrong and Hilditch, 1925; Hilditch and Vidyarthi, 1929]. The acids given in Table V, if mixtures of oleic and octadecadienoic acids, must still contain about 75 % of oleic acid, so that the oxidation products of their esters would include considerable proportions of *n*-nonanoic acid. Nevertheless, it was decided to investigate the mixture of acids obtained from their oxidation, since it appeared impracticable to obtain a higher concentration of the polyethenoid acids.

The acids of fractions E and F (Table V, i.v. 113.5) were converted into methyl esters (25 g., i.v. 108.2), which were dissolved in boiling acetone (250 ml.) and gradually oxidised with finely powdered potassium permanganate (100 g.). After refluxing for an hour after the addition of permanganate was completed, the acetone was removed and the residual product powdered and mixed with sodium bisulphite (120 g.). Water (200 ml.) was then cautiously added, followed by 50 % sulphuric acid (240 g.) in order to effect decoloration and solution of manganese oxides. The solution was extracted with ether and the ether washed twice with water (the aqueous solution and washings (A, *v. infra*) were united and reserved). The ethereal solution was then thoroughly extracted with 10 % aqueous potassium carbonate and subsequently washed with water, the alkaline extract and washings (B) being united and reserved. The ether contained 8.2 g. of unchanged or partially oxidised neutral esters (i.v. 63.6).

The aqueous extracts A were distilled in steam, the condensate being thoroughly extracted with ether. The ethereal extract was dried over sodium sulphate for 2 weeks, and the ether was then removed by distillation. A very small amount of residue was left which possessed the characteristic smell of ethyl acetate and distilled almost completely at 78°; the amount of distillate was however too small for further examination.

The potassium carbonate extracts and washings B were made acid with dilute sulphuric acid and were then also distilled in steam for some hours. The residue from the steam-distillation was hydrolysed by aqueous caustic potash and subsequently made acid, somewhat impure azelaic acid (8 g., M.P. 98°) being obtained; we were not able to detect the presence of any other dicarboxylic acid. (The complete oxidation of 16.8 g. of unsaturated ( $\Delta^{9,10}$ ) C<sub>18</sub> esters would result in the production of 10.7 g. of azelaic acid.) The condensate (*ca.* 1500 ml.) from the steam distillation was extracted with ether and the ether extract dried as under (A); after removal of the ether the residue was fractionally distilled from a plain Willstätter bulb at atmospheric pressure with the results shown in Table VII.

Table VII.

Fraction	g.	B.P./760 mm.	Equiv. wt.
1	0.35	85–100°	604.0
2	0.69	100–200	137.5
3	0.74	200–210	131.1
4	1.74	210–230	139.2
5	1.77	230–237	148.9
6	1.04	Residue	163.7
	<u>6.33</u>		

Fraction 1 was obviously mainly water with some ether. Fraction 2 also evidently still contained a little water, but the greater part of this fraction came

over at 190–200°, and steady boiling only set in at this point. From this, and the fact that the lowest equiv. wt. observed was 131.1, we feel confident that no acid lower than *n*-hexanoic (mol. wt. 116, B.P. 205°) was present in any quantity. If we assume that the acids in fractions 2–5 were mixtures of *n*-hexanoic and *n*-nonanoic, the total yield of *n*-hexanoic acid would be 1.74 g., corresponding with 4.41 g. of a methyl  $\Delta^{9,10,12,13}$ -octadecadienoate; the amount of the latter ester in the 25 g. of esters oxidised (again supposing this to be a mixture of methyl oleate and octadecadienoate) would have been 6.43 g.

An alternative supposition consistent with the above observations (Table VII) is that *n*-heptanoic acid was the member of lower mol. wt.; in this case the acid from which it was derived would have been the conjugated  $\Delta^{9,10,11,12}$ -octadecadienoic acid. The quantity and ease of isolation of the recovered azelaic acid were quite similar to those in many cases we have had occasion to examine in which ordinary methyl oleate-linoleate mixtures have been submitted to this oxidation. Our present results therefore seem to fix the unsaturation in the polyethenoid acids as lying between the ninth and the twelfth or thirteenth atoms in the carbon chain (counting from the carboxyl carbon). This definitely limits the acid or acids in question to the diethylenic series.

We felt however that the detection of small amounts of ethyl acetate merited further attention, since, if the acetic acid had resulted from the decomposition of malonic acid formed during the oxidation, this would be evidence of the original presence of the grouping—CH:CH.CH<sub>2</sub>.CH:CH—. (The occurrence of ethyl acetate, rather than free acetic acid, is readily to be accounted for by esterification of the latter, by alcohol present in the ether<sup>1</sup>, during the prolonged desiccation of the ether solutions by anhydrous sodium sulphate.) The following additional experiments were therefore undertaken in order to ascertain the origin of the acetic acid.

"Blank" oxidations with potassium permanganate and acetone. In two separate experiments, the acetone as used in the previous oxidation (250 ml.) was refluxed with finely powdered potassium permanganate (10 g.) for 2 hours, after which the acetone was distilled and the residues were worked up exactly as when the butter ester-fractions had been oxidised. In neither case was any distillate boiling below 100° obtained from the dried ether extracts of the respective steam-distillates, nor was any odour of ethyl acetate or acetic acid detectable; the only products obtained were very small amounts of liquid (B.P. > 140°), which from their odour appeared to consist of mesityl oxide or similar condensation products.

Control oxidation with pure methyl oleate. A specimen of pure methyl oleate (25 g.), from oleic acid which had been freed from linoleic acid by crystallisation of its lithium salt, was oxidised, and the products were worked up, exactly as in the case of the above experiment, 6.3 g. of unchanged or semi-oxidised neutral ester (i.v. 62.4) being recovered. No distillable products were obtained from the steam distillation of the aqueous washings (A, p. 1569) and no odour of ethyl acetate or acetic acid could be detected, but the minute amount of liquid residue had the characteristic odour of ethyl nonanoate. Similarly, no acetic acid or ester could be detected in the extract from the steam-distillation of the acids produced after hydrolysing the alkali-soluble products of oxidation (B, p. 1569). The distillation of these products is summarised in Table VIII.

<sup>1</sup> It is our practice to add alcohol, during the extractions with alkali, in order to diminish emulsification.

Table VIII.

*Oxidation of C<sub>18</sub> unsaturated ester-fractions from ground-nut oil acids.* Finally, the unsaturated acids of ground-nut oil were isolated by the lead salt-alcohol separation, and their methyl esters fractionally distilled. The C<sub>18</sub> ester fractions so obtained had i.v. 111.7, i.e. their mean unsaturation was comparable with that of the butter ester-fraction which had been oxidised, whilst in this instance it was known that the polyethenoid derivative present was the ester of ordinary or seed fat  $\Delta^{9,10,12,13}$ -octadecadienoic acid. On oxidation exactly as in the previous instances, 11.5 g. of unchanged or semi-oxidised neutral esters (i.v. 78.2) were recovered from the 25 g. of esters taken. The extract (A) from the steam-distillate of the aqueous washings yielded 3.4 g. of a liquid, B.P. 78-82°, which was neither acid nor ester and appeared to consist mainly of alcohol: in this case no smell of ethyl acetate or of acetic acid (other than a slight "pyroligneous acid" odour) was observed in this fraction.

The result of the corresponding distillation of the extract (B) from the steam-distillate of the acids obtained after hydrolysis of the alkaline washings is shown in Table IX.

\* Determined after extraction of acidic matter from the charred residue by aqueous potassium carbonate, followed by recovery of the extracted acids.

Fraction 1 smelled strongly of ethyl acetate and acetic acid and fractions 2-3 of the latter. The boiling-points and equiv. wt. of fractions 2 and 3, considered together, also suggest that a mixture of acetic with acids of much higher mol. wt. was coming over at this stage. These fractions were united, dissolved in ether and extracted with water to effect as much separation as possible of any acetic acid present; the recovered acids (0.94 g.) had equiv. wt. 125.8. In this experiment the acetic acid thus appeared in fraction "B" rather than "A". Apart from this, the character of the acids in fractions 4-7 closely resembles that of those obtained in the corresponding distillation (Table VII) of the monobasic acids from the oxidation of the butter ester-fraction.

Calculated on a mixture of *n*-hexanoic and *n*-nonanoic acids, the fractions 4-7 (with the recovered 0.94 g. of acids from fractions 2 and 3) contained 2.14 g. of *n*-hexanoic acid, corresponding with 5.42 g. of methyl  $\Delta^{9,10,12,13}$ -octadecadienoate. The amount of the latter ester in the 25 g. of ground-nut oil esters oxidised (i.v. 111.7) is 7.44 g.

Comparing the oxidation of the ground-nut oil esters (Table IX) with those of the butter esters of similar mean unsaturation (Table V), and assuming that the latter were also mixtures of methyl oleate with a methyl  $\Delta^{9,10,12,13}$ -octadecadienoate, the respective proportions of octadecadienoic ester accounted for as *n*-hexanoic acid are 73 % (ground-nut oil esters) and 69 % (butter esters). This similarity is accompanied by a general parallelism in the mol. wt. of the distilled acid fractions of corresponding boiling-point in the two series. In these respects, and in the appearance of acetic acid (or ester), the two experiments are remarkably comparable and the results point to the conclusion that an octadecadienoic acid of the same structure (but not necessarily the same configuration) is present in cow butter fat and in ground-nut oil.

Little significance would be attached to the appearance of small amounts of acetic acid in the oxidation products were it not for the fact that, in the products from the corresponding experiments with pure methyl oleate or with acetone alone, acetic acid was not detected in any instance. These negative observations, on the other hand, justify the conclusion that, in the ground-nut oil esters, the acetic acid results from the  $\Delta^{9,10,12,13}$ -octadecadienoate present (by decomposition of malonic acid formed in the course of the oxidation). The similar appearance of acetic acid in the oxidation products of the butter esters must therefore be ascribed to the same cause.

The potassium permanganate-acetone oxidations of the  $C_{18}$  unsaturated butter esters from the acid fractions in which the polyethenoid acids had been concentrated as far as possible by the lithium salt separation thus support the view that a  $\Delta^{9,10,12,13}$ -octadecadienoic acid is present therein in some quantity.

*Oxidation of the unsaturated acids of cow butter fat by  
aqueous alkaline potassium permanganate.*

We have found, in the course of oxidations with aqueous alkaline permanganate carried out according to the modified Hazura procedure described in the preceding paper [1935], that the acids from the unsaturated  $C_{18}$  ester fractions with which we have been dealing give rise to small quantities of the crystalline tetrahydroxystearic acids which correspond with seed fat linoleic acid. In common with other workers, we had formerly been unable to isolate any of these acids from the alkaline oxidation of butter acids. The quantities now obtained are but small and only represent a fraction of the total octadecadienoic acids which we believe to be present; but they have been detected in each case in which the alkaline permanganate oxidation described in the preceding paper has been applied either to the acids from the unsaturated  $C_{18}$  ester fractions or to acids obtained from the latter in which the polyethenoid members had been concentrated by the lithium salt process. Moreover, study of these fractions from butters taken at various seasons over a number of years has shown that production of the typical crystalline tetrahydroxystearic acids is at a minimum in summer pasture butters and at a maximum at the end of the winter season.

A summary of these experiments is given in Table X. As far as possible, the same weight of unsaturated acids was oxidised in each instance, so that the weights of tetrahydroxystearic (water-soluble) acids isolated give a direct comparison of the respective yields (except for unavoidable differences in i.v., or rather, in the proportions of mono- and di-ethenoid acids, of the original mixture). For further illustration, the final column of relative yield percentages has been added: this gives the amount of linoleic acid, corresponding to the tetrahydroxystearic acids obtained, expressed as a percentage of the total

Table X. *Crystalline tetrahydroxystearic acids obtained by alkaline permanganate oxidation of unsaturated C<sub>18</sub> ester fractions from summer and winter butters.*

\* Acids G (p. 1567) from lithium salt process.

† Oxidation by Lapworth-Mottram procedure.

octadecadienoic acid present (the I.V. of the original acid fractions being assumed, for this purpose, to be due only to oleic and octadecadienoic acids).

The water-soluble acids isolated were shown to be mixtures of the two characteristic tetrahydroxystearic acids, M.P. 155° and 172°. Thus, the acids, M.P. 143–157°, from the winter butter of February 1934 (0.091 g.), when heated with ethyl acetate, yielded an insoluble portion (0.027 g., M.P. 170–172°), whilst the filtrates gave two successive crops of crystals: 0.033 g., M.P. 154°, and 0.013 g., M.P. 114–117°.

Since, as shown by the study of their bromo-addition products (p. 1568), the unsaturated acids in Table X include a very small proportion (not more than 1 %) of acids with more than two ethenoid linkages, the true yield of the two crystalline tetrahydroxystearic acids in terms of octadecadienoic acid will be slightly greater than shown in the final column, but it is still far below the figure of about 40 % of theory given alike by seed fat linoleic acid or the related "α"-linoleic acid (*cf.* preceding paper, p. 1555). From these figures, ordinary linoleic acid cannot form more than about one-fifth of the octadecadienoic acids in the summer pasture butters, but in the winter butters it rises to about a third of the total octadecadienoic acids. The definitely higher proportions in the winter butters are probably significant in relation to the diet of the cows at this period, which of course includes roots and a much higher ratio of concentrates (grain) than when the cows are at pasture.

Smith and Chibnall [1932], in their investigation of the glyceride fatty acids of cocksfoot grass, found that the unsaturated acids (I.V. 185.3) did not yield the crystalline tetrabromostearic acid, M.P. 114°, although 8.9 g. of oily tetrabromo-derivatives insoluble in cold light petroleum (B.P. 40–60°) resulted from 10.4 g. of the unsaturated acids. They inferred the presence of a mixture of isomeric tetrabromostearic acids. Again, they obtained only 0.45 g. of mixed crystalline tetrahydroxystearic acids when 11 g. of the unsaturated acids were oxidised with alkaline permanganate according to the Lapworth-Mottram procedure, corresponding to an apparent content of only 3.3 % of ordinary linoleic acid. Their experiences thus resemble ours with the pasture butter unsaturated fatty acids to a remarkable degree, and we consider that the peculiarities of the

butter octadecadienoic acids are the consequence of their derivation from grass glycerides by direct assimilation. This opinion is reinforced by the recent observations of Bosworth [1934] on human milk fat: he obtained fractions of unsaturated  $C_{18}$  acids which yielded without difficulty the tetrabromostearic acid, m.p.  $113^{\circ}$ , insoluble in light petroleum. The consensus of all these observations is clearly that absence of, or diminution in the proportion of, ordinary linoleic acid in milk fats is paralleled by the extent to which grass has formed a component of the diet, while the grass glycerides themselves have been found by Smith and Chibnall to exhibit similar anomalies as regards the type of octadecadienoic acid present.

At this point we would make a more general observation with reference to the appearance of linoleic or other octadecadienoic acids in the fats of most of the land animals, namely, that recent work suggests that these acids are probably invariably derived by assimilation and not by synthesis in the animal from non-fatty compounds. The results obtained in the past few years in this laboratory on various land animals have led to the conclusion that, so far as concerns palmitic and oleic acids (and, at least in the herbivora, the approximately constant stearic-oleic acid balance), these glyceride components can be produced by the animal, and in such manner that the palmitic content is closely similar (25–30 %) for all animals, whilst the stearic and oleic contents vary with the animal, or even with the site in which the fat is deposited. On the other hand, the following observations accord with the hypothesis that in land animal glycerides octadecadienoic acids are the result of assimilation:

(a) *Cow and human milk-fats.* The relevant data in these cases have been presented above.

(b) *Pig depot fats.* Young pigs (8–10 months old) on fat-free or low-fat diets yield body fats with only 1–5 % of combined linoleic acid [Ellis and Zeller, 1930; Bhattacharya and Hilditch, 1931]; the corresponding fats of older animals (4–8 years) contain as much as 14–15 % of linoleic acid, and this proportion is unaltered in fats from different parts of the same animal which differ considerably in their relative contents of oleic and stearic acids [Banks and Hilditch, 1932; Dean and Hilditch, 1933]. (The linoleic acid of pig fats gives the ordinary tests as regards tetrabromo- and tetrahydroxy-stearic acids [Hilditch and Stainsby, 1935]).

Further, young pigs fed on rations high in fatty oils such as those of cotton-seed, ground-nut or soya bean yield depot fats with abnormally high contents of linoleic acid [Ellis *et al.*, 1925; 1926; 1931].

(c) *Rat depot fats.* With fat-free diets, the depot fats of rats are devoid of linoleic acid, but ingestion of cod-liver oil leads to the appearance of linoleic glycerides in the depot fats [Burr and Burr, 1930; Gregory and Drummond, 1932; Banks *et al.*, 1933].

We hope to make a similar examination in the near future of the polyethenoid  $C_{18}$  acids present in small quantities in the depot fats of oxen which have been reared under known dietary conditions.

#### SUMMARY.

A further examination has been made of the polyethenoid  $C_{18}$  acids in cow butter fat. The acids were prepared by refractionation of the esters of the butter "liquid" acids, followed by separation of the more soluble lithium salts from alcohol;  $C_{18}$  acids with i.v. 113.4–114.8 were thus obtained and used in the experiments described.

Addition of bromine to the acids of I.V. 114.8 led to a mixture of bromo-addition products, 1.6 % of the original acids giving products insoluble in cold ether or light petroleum, whilst the remaining 98.4 % yielded liquid bromo-addition products (Br 40.0 %) soluble in cold light petroleum. It is shown that these are unlikely to include any appreciable amount of hexa- or octa-bromostearic acids and that, accordingly, the original acids contained about 75% oleic, 1.5 % tri- or tetra-ethenoid C<sub>18</sub> acids, and 23.5 % octadecadienoic acid.

Examination of the acids formed as a result of oxidation of the methyl esters of acids of I.V. 113.5 by permanganate in acetone showed that the monobasic acids (*n*-hexanoic or *n*-heptanoic, *n*-nonanoic and small quantities of acetic) resembled, qualitatively and quantitatively, those obtained by similar treatment of a fraction of the unsaturated esters from ground-nut oil (of similar I.V.); while the amount of azelaic acid recovered showed that unsaturation did not commence before the ninth carbon atom from the carboxyl group. Control experiments with pure methyl oleate in acetone, or with acetone alone, failed to yield any acetic acid. These experiments therefore suggest that the octadecadienoic acids of ground-nut oil and cow butter fat are structurally similar, and that the latter is a different geometrical isomeride (or mixture of geometrical isomerides) of the  $\Delta^{9,10,12,13}$ -octadecadienoic acid of seed fats.

Oxidation of unsaturated C<sub>18</sub> acid fractions from a number of butters by means of aqueous alkaline permanganate (*cf.* preceding paper) led in all cases to the isolation of small proportions of the same mixture of tetrahydroxystearic acids as that which is thus obtained in a yield of about 40 % from seed fat linoleic acid. The amount of these acids obtained from butters from cows on winter diet was considerably (*ca.* 50 %) greater than that from summer pasture butters.

It is concluded that the kind of octadecadienoic acid present in butter fat depends upon the diet of the cows and, since the bromination and alkaline oxidation results in this investigation are closely parallel with those of Smith and Chibnall on the glyceride fatty acids of grasses, that the peculiarities of butter fat octadecadienoic acid are the consequence of assimilation of the same acid from the grass glycerides.

Study of the data now available in the cases of cow and human milk fats and of the depot fats of pigs and rats has led us to the general conclusion that linoleic acid, when present in the glycerides of land animals, is a product of assimilation and not of synthesis by the animal.

# CLXXXIX. THE HYDROLYSIS OF THE COMBINED FORMS OF OESTRONE AND OESTRIOL PRESENT IN HUMAN PREGNANCY URINE.

BY SAUL LOUIS COHEN AND GUY FREDERIC MARRIAN.

*From the Department of Biochemistry, University of Toronto, Canada.*

*(Received April 17th, 1935.)*

FOR several years it has been recognised that the yields of oestrogenic material which can be obtained from human pregnancy urine by extraction with immiscible fat-solvents may be considerably increased by preliminary acidification of the urine [Marrian, 1930; 1933; Doisy *et al.*, 1930]. Zondek [1934, 1] did, indeed, state that such preliminary treatment was unnecessary to ensure complete extraction of the hormones, but later [1934, 2] revised his opinions as a result of work carried out by Borchardt *et al.* [1934]. The latter authors were responsible for the first systematic attempt to determine the optimum conditions for the liberation of oestrin from its combined state in human pregnancy urine. They showed that the amount of hormone that could be extracted by prolonged boiling with benzene was greatly increased by acidification of the urine to  $p_H$  3.0, and still further increased by the addition of hydrochloric acid to a concentration of 3.6 %.

The present authors [1934] developed a colorimetric method, based on the Kober test [1931] for oestrin, for the separate quantitative estimation of oestrone and oestriol in ethereal extracts of human pregnancy urine. This method enabled a more complete study of the factors influencing the hydrolysis by acids of the "oestrin-esters" in urine to be made than would have been possible if only the biological test for oestrin had been available. It was shown that when pregnancy urine was acidified to  $p_H$  1-2 and then heated at 100°, there occurred a slow liberation of ether-soluble oestrin from the combined form, which reached a maximum after 16 hours. Heating for longer periods resulted in a decrease in the amount of ether-extractable oestrin, indicating that destruction of the liberated hormone had occurred. By heating the urine acidified to  $p_H$  1-2 in an autoclave at 15 lbs. pressure for 2-4 hours, a larger amount of ether-soluble oestrin was liberated than when the urine was heated at 100°. Autoclaving for longer periods destroyed the liberated oestrin. This work clearly showed that, as might be expected, the rate of hydrolysis of the "oestrin esters" in urine is considerably increased by an increase in temperature, and that destruction of the hormone may occur on prolonged heating in an acid aqueous medium.

Few attempts have been made to effect liberation of the combined oestrin in urine by means other than that of hydrolysis with acids. Marrian [1933] found that keeping the urine until considerable bacterial decomposition had occurred was extremely effective as a means of liberating the combined oestrin, but that heating to 100° at an alkaline reaction for short periods was ineffective. Both these findings were confirmed by Cohen and Marrian [1934].

For two reasons it was clearly necessary to conduct a more detailed investigation of the factors involved in the hydrolysis of the "oestrin esters" in human pregnancy urine. In the first place, estimation of the oestrin content of urine

either by direct biological assays on the whole urine<sup>1</sup> or by colorimetric or biological assays on ethereal extracts, must necessarily be extremely inaccurate unless the conditions for optimum hydrolysis with minimum destruction are known. In the second place, data on the stability of the "oestrin esters" to mild treatment with acids and alkalis were required in order to devise methods for their isolation in a state of purity. To these ends therefore the effects of temperature and  $p_H$  (both acid and alkaline) on the rates of hydrolysis of the "esters" and on the rates of the destruction of the liberated oestrins have been studied in greater detail. Experiments have also been conducted to determine the nature of the destruction caused by prolonged hydrolysis.

*Hydrolysis of the "oestrin esters" by acid.*

(1) *The effect of temperature.* A finding of some practical importance has been that acid hydrolysis is almost undetectable at temperatures at or near 0°. Urines acidified to  $p_H$  1.0 and stored for several weeks in the ice-box showed no appreciable increase in ether-soluble oestrin. The present experiments confirm the fact that for rapid and effective acid hydrolysis of the "oestrin esters" heating at about 120° in an autoclave is preferable to heating at 100°.

(2) *The effect of acidity.* As would be expected, the rate of hydrolysis of the "oestrin esters" is greatly increased with an increase in hydrogen ion concentration. Quantitative study of the effect of variations in  $p_H$  was however complicated by the fact that during hydrolysis the  $p_H$  of the urine increased very considerably owing to the formation of ammonia by the decomposition of urea. For instance a urine acidified to  $p_H$  1.0 and then heated at 120° for 1 hour, may have a final  $p_H$  as high as 7. Since the extent of this change in  $p_H$  depends upon the urea content of the urine, which may be extremely variable, it has not been possible to determine the exact initial  $p_H$  of the urine necessary for optimum hydrolysis. It has been found however that maximum hydrolysis results after 2 hours' heating at 120°, when the final  $p_H$  of the urine is 1.0. In order to attain the conditions necessary to arrive at this final  $p_H$ , it is sufficient for the majority of urine samples to acidify to  $p_H$  1.0 and then to add 3.3 ml. of 12*N* HCl per 100 ml. of urine. The concentration of urea may be so high in some specimens however that this excess of acid is insufficient to keep the final  $p_H$  to 1.0 or less. It is therefore essential to determine the  $p_H$  of the urine after hydrolysis, and if necessary to repeat the hydrolysis with a larger excess of acid. It must be emphasised however that the addition of too large an excess of acid is to be avoided, since the rate of destruction of the liberated oestrin is greatly increased with increased acidity (see following section).

(3) *Destruction of the oestrins by heating in acid solution.* Destruction of liberated oestrone and oestriol in urine by prolonged heating in acid solution was found to be considerably increased by an increase in temperature. A urine completely hydrolysed with respect to its "oestrin esters" was found to suffer little loss in liberated oestrin when stored in the ice-box at  $p_H$  1.0 for several days. At 100° the rate of destruction was significantly more rapid. In one case 35 % of the total oestrin was destroyed by heating at  $p_H$  1.0 for 20 hours longer than was necessary for complete hydrolysis of the esters. The rate of destruction was still further increased by heating at 120°.

In an early experiment it had been noticed that destruction of oestrin in a sample of acidified urine heated at 120° was greater when the autoclave was

<sup>1</sup> Preliminary experiments have shown that the combined forms of oestrone and oestriol in urine are much less active than the free forms in inducing vaginal cornification in ovariectomised mice.

opened at intervals during the hydrolysis than when the hydrolysis was allowed to proceed uninterruptedly for the same total time. This suggested that the oxygen absorbed by the urine from the air might be a factor in the destruction of the oestrin. Experiments were therefore conducted to test this possibility. It was found that the rate of destruction of oestrin during hydrolysis could be greatly increased by shaking the urine with air at intervals and still further increased by periodic saturation with oxygen. Thus it seems extremely probable that the destruction of oestrone and oestriol which occurs in prolonged heating of acidified urines is oxidative in character. It should be pointed out that destruction of oestriol in acid solution has invariably been found to be more rapid than destruction of oestrone under the same conditions. The possibility remained that this destruction might be caused through the agency of some constituent of the urine rather than by direct oxidation of oestrone and oestriol. It was shown however that marked destruction of pure oestrone and oestriol resulted when they were heated in aqueous acid solution. In this case destruction of oestriol was again observed to be more rapid than that of oestrone.

The practical significance of these findings is considerable. In order to carry out an estimation of the oestrin content of urine with any degree of accuracy, the conditions for acid hydrolysis must be such that maximum hydrolysis of the "esters" and minimum destruction of the liberated oestrin results. Actually it is difficult to obtain complete hydrolysis of the "esters" without some destruction of the free oestrin even when precautions against access of oxygen to the urine are observed. It has been found however that if the urines are heated to 120° for 2 hours after proper acidification (see previous section) the hydrolysis of the "esters" is complete as far as can be determined, whilst the destruction is not sufficiently great to introduce a serious error into the estimation.

#### *Hydrolysis of the "oestrin esters" by alkali.*

As has been previously mentioned, earlier work showed that heating alkaline urine to 100° for short periods was ineffective in causing hydrolysis of the combined forms of the oestrogens. In the present work it has been shown that under more vigorous conditions slow hydrolysis of the "esters" does occur. After heating at 100° for 8 hours a urine sample containing NaOH at *N* concentration, a slight but perceptible degree of hydrolysis of the "esters" occurred. When such alkaline urines were heated at 120° in an autoclave the hydrolysis was considerably more rapid. During the first few hours a fairly rapid hydrolysis of both oestrone and oestriol "esters" was observed, so that at the end of 4 hours of heating approximately half of the total oestriol was liberated, while the proportion of oestrone "ester" hydrolysed under these conditions varied considerably with different urine samples, being complete in some cases and only about half complete in others. The oestrone and oestriol "esters" remaining unhydrolysed after 4 hours were found to be remarkably resistant to further hydrolysis even after the addition of more alkali. This curious state of affairs could not be explained on the grounds that the apparently unhydrolysed esters were destroyed, since by subsequent acid hydrolysis the remaining oestrone and oestriol were nearly quantitatively recovered. A possible explanation seemed to be that there were present in the urine two different types of oestrin esters, one of which was readily hydrolysed by alkali while the other was alkali-stable. This explanation would have been acceptable if it had not been for the fact that on more than one occasion it was observed that when a second sample of the urine was worked up some time after the first, there was a significant

difference in the relative proportions of the alkali-labile and alkali-stable forms. At present no explanation of this curious phenomenon can be given.

After heating alkaline urines at 120° for periods longer than were necessary to give optimum hydrolysis of the "esters" it was observed that there was a slow decrease in the amounts of ether-extractable oestrone and oestriol. Experiments carried out by heating solutions of pure oestrone and oestriol in *N* NaOH showed that destruction of the hormones occurred. It may be noted that the oestrin destroyed in this way cannot be recovered by subsequent acid hydrolysis, so that this phenomenon of slow destruction by heating with alkali is entirely distinct from the phenomenon of the incomplete hydrolysis of the "esters" by alkali referred to above. It was also shown that this alkaline destruction, like that caused by acids, is oxidative in nature.

#### EXPERIMENTAL.

##### (1) *The effect of temperature on the rate of hydrolysis of "oestrin esters" in human pregnancy urine.*

300 ml. samples of urine were adjusted to the desired  $p_H$  by addition of 12 *N* HCl. The samples to be hydrolysed at 6° were placed in the ice-box; those to be hydrolysed at 100° and 120° were heated in a boiling water-bath and in an autoclave under 15 lbs. pressure respectively. The oestrone and oestriol in the hydrolysed urines were extracted, separated and estimated colorimetrically in the manner previously described [Cohen and Marrian, 1934]. Determinations of the amounts of free ether-soluble oestrone and oestriol were made in both batches of urine. The results are shown in Table I.

Table I.

Urine batch	Hydrolytic treatment			mg. oestrin per 100 ml. urine			
	$p_H$	Temp. °C.	Time hours	Before hydrolysis		After hydrolysis	
				Oestriol	Oestrone	Oestriol	Oestrone
P.U. 11	3.0	6	336	0.005	0.007	0.008	0.003
	1.0	6	336	0.005	0.007	0.008	0.002
	1.0	120	4	0.005	0.007	0.642	0.083
P.U. 8	1.0	100	4	0.085	0.019	0.750	0.100
	1.0	120	4	0.085	0.019	1.000	0.125

Table II.

Urine batch	$p_H$		mg. oestrin liberated per 100 ml. urine	
	Initial	Final	Oestriol	Oestrone
P.U. 11	3.0	6.0	0.008	0.006
	1.0	4.5	0.220	0.045
I.P.U. 6 B	1.0	4.0	0.400	0.060
	1.0	<1.0	1.420	0.100
P.U. 12	+ 10 ml. HCl			
	1.0	4.5	0.163	0.030
	1.0	1.0	0.290	0.045
	+ 3 ml. HCl			
	1.0	<1.0	0.420	0.060
	+ 5 ml. HCl			
	1.0	<1.0	0.550	0.070
	+ 10 ml. HCl			
	1.0	<1.0	0.800	0.080
	+ 20 ml. HCl			

(2) *The effect of acidity on the rate of hydrolysis of "oestrin esters".*

300 ml. samples of urine were acidified to  $p_H$  1.0 (in one case to  $p_H$  3.0) by the addition of 12 *N* HCl. To certain of these samples different excesses of 12 *N* acid were added. All the samples were then heated for 1 hour in the autoclave at 120°. The final  $p_H$  of the hydrolysed urine was measured and the liberated oestrone and oestriol were determined as usual. In each case control estimations on unheated acidified urines were carried out in order to determine the amounts of ether-soluble oestrone and oestriol initially present. The results are shown in Table II.

(3) *The effect of acidity on the rate of destruction of oestrin liberated by hydrolysis from the combined form in pregnancy urine.*

1200 ml. of urine (batch P.U. 12) were adjusted to  $p_H$  1.0 and then divided into four 300 ml. samples. To three of these 5, 10 and 20 ml. excess of 12 *N* HCl were added respectively. All four samples were then autoclaved at 120° for 4 hours. The samples were removed from the autoclave after 1 and 2 hours for readjustment of the  $p_H$  to 1.0; this readjustment was necessary only for the sample to which no excess of acid had been added. The oestrone and oestriol in each sample were then estimated in the usual manner. The results are shown in Table III. It will be seen that the sample heated for 4 hours at an approximately constant  $p_H$  of 1.0 gave nearly the same oestrone and oestriol values as were obtained by heating the urine for 1 hour with a larger excess of acid (see Table II). The 4 hours' heating with a large excess of acid caused considerable destruction of the oestrin, the amount of destruction being greater in the more strongly acidified samples.

Table III.

ml. 12 <i>N</i> HCl added to 300 ml. urine at $p_H$ 1.0	mg. oestrin per 100 ml. urine after 4 hours' heating		% destruction	
	Oestriol	Oestrone	Oestriol	Oestrone
0	0.625	0.090	0	0
5	0.583	0.087	7.0	3.3
10	0.508	0.082	20.0	9.0
20	0.416	0.072	34.0	20.0

(4) *The effect of oxygen on the rate of destruction of oestrin in urine by acid.*

Three 300 ml. samples of urine (batch P.U. 13) were strongly acidified by the addition of 10 ml. of 12 *N* HCl after adjusting to  $p_H$  1.0. One sample was heated continuously in the autoclave at 120° for 4 hours. A second sample was heated to 120° for four separate periods of 1 hour, being shaken thoroughly with air before each period. A third sample was also heated for four separate periods of 1 hour, but before each period it was thoroughly saturated with oxygen. Ether-soluble oestrone and oestriol were estimated in each after the hydrolyses. As a control, a fourth sample of urine was hydrolysed under conditions which give maximum liberation of free oestrin. A similar experiment was conducted on another batch of urine (P.U. 14) after a greater degree of acidification. The results are shown in Table IV.

Table IV.

Urine batch	ml. 12N HCl added to 300 ml. urine at $p_H$ 1.0	Hydrolytic treatment at 120°	mg. oestrin per 100 ml. urine after hydrolysis		% loss	
			Oestriol	Oestrone	Oestriol	Oestrone
P.U. 13	*12	2 hours continuously	0.650	0.082	—	—
	10	4 hours continuously	0.675	0.083	0	0
	10	4 periods of 1 hour, shaking with air	0.600	0.080	11.0	4.0
	10	4 periods of 1 hour, saturation with oxygen	0.550	0.078	19.0	6.0
P.U. 14	*10	2 hours continuously	1.000	0.090	—	—
	20	4 hours continuously	0.865	0.090	13.5	0
	20	4 periods of 1 hour, shaking with air	0.642	0.085	35.8	5.6
	20	4 periods of 1 hour, saturation with oxygen	0.517	0.068	48.3	24.4

\* Control experiments upon which the % losses in the last two columns are calculated.

(5) *The destruction of pure oestrone and oestriol by heating in acid solution.*

Aqueous solutions containing known amounts of oestrone and oestriol were prepared by the addition to water of small volumes of strong alcoholic solutions of the two compounds. The oestrone and oestriol in one such solution of 200 ml. were estimated directly without any further treatment. The losses due to the extractions were within the range of experimental error of the method of assay. To each of five other 200 ml. volumes of such solutions were added 20 ml. of 12N HCl. Two of these solutions were then heated at 120° in the autoclave for 3 hours continuously, three were autoclaved for three periods of 1 hour each, one being shaken with air before each period, while the remaining two were saturated with oxygen before each period of autoclaving. The oestrone and oestriol in each were then determined as usual. The results are shown in Table V.

Table V.

mg. oestrin initially present in aqueous solution		ml. 12N HCl added	Hydrolytic treatment at 120°	mg. oestrin recovered		% loss	
Oestriol	Oestrone			Oestriol	Oestrone	Oestriol	Oestrone
1.000	0.100	0	None	0.870	0.106	13.0	0
0.808	0.132	20.0	3 hours continuously	0.510	0.120	37.0	9
0.808	0.132	20.0	3 periods of 1 hour, shaking with air	0.390	0.110	52.0	17.0
0.808	0.132	20.0	3 periods of 1 hour, saturation with oxygen	0.210	0.065	74.0	50.0
—	0.200	20.0	3 hours continuously	—	0.157	—	17.2
—	0.200	20.0	3 periods of 1 hour, saturation with oxygen	—	0.083	—	58.5

(6) *The effect of temperature on the rate of hydrolysis by alkali of "oestrin esters".*

To 300 ml. samples of pregnancy urine were added 35 ml. of 40 % NaOH. The samples were then heated at 100° or 120° for the required periods. After acidification to litmus, the mixtures were extracted and the oestrone and oestriol liberated by the hydrolysis determined as usual. Control samples of each batch

of urine so treated were acid-hydrolysed under optimum conditions in order to determine the total amounts of oestrone and oestriol present. The results are shown in Table VI.

Table VI.

Urine batch	Heating conditions		mg. liberated per 100 ml. urine by alkaline hydrolysis		Total oestrin present in combined form per 100 ml. urine		% hydrolysis by alkali	
	Temp. °C.	Time hours	Oestriol	Oestrone	Oestriol	Oestrone	Oestriol	Oestrone
P.U. 7	100	8	0.086	0.013	0.677	0.058	12.7	22.4
	100	2	0.022	0.003	0.677	0.058	3.2	5.2
P.U. 12	120	2	0.110	0.047	0.610	0.090	18.0	52.2

(7) *The effect of concentration of alkali on the rate of hydrolysis of "oestrin esters".*

To each of four 200 ml. samples of pregnancy urine (P.U. 16) were added 10, 25, 50 and 100 ml. respectively of 40 % NaOH. The samples were autoclaved in nickel crucibles<sup>1</sup> at 120° for 11 hours, acidified to litmus with HCl and assayed for oestrone and oestriol as usual. The maximum amounts of oestrone and oestriol obtainable by acid hydrolysis under optimum conditions were determined in a separate sample of the same urine. From these figures the percentage hydrolysis of the "ester" by alkali in each experiment was determined. It will be seen from the results shown in Table VII that increasing the amount of alkali from 10 to 50 ml. per sample caused increased hydrolysis of the esters. Further increase in the alkali concentration however did not increase the hydrolysis. It will be further seen that the maximum hydrolysis obtainable by alkali is considerably less than the maximum hydrolysis obtained by acid.

Table VII.

ml. 40 % NaOH added to 200 ml. of urine	mg. total oestrin per 100 ml. determined by acid hydrolysis		mg. oestrin per 100 ml. liberated by alkaline hydrolysis		% hydrolysis by NaOH	
	Oestriol	Oestrone	Oestriol	Oestrone	Oestriol	Oestrone
10	1.06	0.170	0.140	0.015	13.1	8.8
25	"	"	0.440	0.087	41.5	51.2
50	"	"	0.538	0.097	50.8	57.0
100	"	"	0.538	0.067	50.8	39.4

(8) *The inability of alkali to effect complete hydrolysis of "oestrin esters".*

To each of three 150 ml. samples of urine (P.U. 17) were added 50 ml. of 40 % NaOH. The samples were then autoclaved at 120° for 4, 8 and 13 hours respectively. After acidification with HCl, the liberated oestrin was extracted and estimated as usual. The acidified urines after extraction were adjusted to  $p_H$  1.0 and further autoclaved for 2 hours in order to hydrolyse the esters which were unattacked by the alkali. An acid hydrolysis of the original urine was also carried out in order to determine the total oestriol and oestrone present. It will be seen from Table VIII that the total amounts of oestrin liberated by alkaline hydrolysis and subsequent acid hydrolysis are identical within the limits of experimental error in each case with the amount of total oestrin as determined in the original urine by acid hydrolysis.

<sup>1</sup> Nickel crucibles were preferable for these alkaline hydrolyses owing to the fact that the strong alkali in the urines rapidly attacked glass.

Table VIII.

mg. total oestrin determined by acid hydrolysis		Period of alkaline hydrolysis hours	mg. oestrin liberated by alkali (A)		mg. oestrin liberated by subsequent acid hydrolysis (B)		(A) + (B)	
Oestriol	Oestrone		Oestriol	Oestrone	Oestriol	Oestrone	Oestriol	Oestrone
1.17	0.060	4	0.43	0.029	0.60	0.064	1.03	0.093
"	"	8	0.55	0.035	0.47	0.058	1.02	0.093
"	"	13	0.59	0.035	0.45	0.056	1.04	0.091

In order to confirm the fact that complete hydrolysis of "oestrin esters" cannot be attained by alkali, a 200 ml. sample of P.U. 16 which had been previously hydrolysed for 11 hours with alkali (see Table VII) and from which the liberated oestrin had been removed by ether extraction, was re-hydrolysed for 4 hours after the addition of 25 ml. of 40 % NaOH. This treatment liberated only 0.029 mg. of oestriol and 0.004 mg. of oestrone. Subsequent acid hydrolysis liberated 0.28 mg. of oestriol and 0.03 mg. of oestrone. \*

(9) *The destruction of pure oestrone and oestriol by heating with alkali in presence of oxygen.*

Two solutions containing 1 mg. of oestriol in 100 ml. of water were prepared. To each were added 30 ml. of 40 % NaOH. One sample was autoclaved at 120° for an uninterrupted 3-hour period. The other was saturated with oxygen and autoclaved for three periods of one hour, the solution being resaturated with oxygen at each interval. Two solutions containing 0.2 mg. of oestrone in 100 ml. of water were similarly treated. After hydrolysis the samples were acidified, and the oestrin was extracted and estimated as usual.

Table IX.

		Hydrolytic treatment	mg. estimated after heating	% destruction
1.0 mg. oestriol		3 hours continuously	0.51	49.0
" "		3 periods of 1 hour, saturation with oxygen	0.06	99.4
0.2 mg. oestrone		3 hours continuously	0.114	42.0
" "		3 periods of 1 hour, saturation with oxygen	0.010	95.0

### SUMMARY.

1. A study has been made of the factors which influence the rate of hydrolysis of the ether-insoluble oestrone and oestriol "esters" present in human pregnancy urine.

2. When urine is adjusted to  $p_H$  1.0, the hydrolysis is negligible at 6°. When the final  $p_H$  of the urine is about 1.0, hydrolysis is complete in about 16 hours at 100° and in 2 hours at 200°. Owing to utilisation of the acid by the hydrolysis of urea, the initial  $p_H$  of the urine must be below 1.0. The rate of hydrolysis of the "esters" is increased by further increasing the acidity of the urine.

3. Destruction of both oestrone and oestriol occurs when they are heated in acid solution in the presence of oxygen. The rate of destruction is increased by increasing the acid concentration and by frequent introduction of oxygen. The rate of such destruction of oestrone is less than that of oestriol.

4. In order to make possible the accurate assay of oestrone and oestriol in pregnancy urine it is necessary to hydrolyse the urine under conditions which

combine maximum hydrolysis of the esters with minimum destruction of the liberated oestrone and oestriol. These conditions are generally fulfilled when the urine is adjusted to  $p_H$  1.0, further acidified by the addition of 3.3 ml. of 12*N* HCl per 100 ml. of urine and autoclaved at 120° for 2 hours. The final  $p_H$  of the urine must however be determined in every case and if it is found to be greater than 1.0, the hydrolysis must be repeated with a larger excess of acid.

5. Hydrolysis of about 50 % of the oestriol "ester" in pregnancy urine can be effected by heating the urine made 2*N* with NaOH to 120° for 6–8 hours. In some, but not in all urines this treatment hydrolyses all the oestrone "ester". Further hydrolysis in the presence of higher concentrations of alkali or for longer periods is ineffective in breaking down the alkali-resistant "ester" fraction. These alkali-resistant "esters" can be subsequently completely hydrolysed by acid. The significance of the incomplete hydrolysis of the "esters" by alkali is not yet understood.

6. Prolonged heating in alkaline solution in the presence of oxygen results in destruction of both oestrone and oestriol.

The authors wish to express their thanks to Dr Melville Watson of the Department of Obstetrics and Gynaecology for his willing co-operation in procuring samples of pregnancy urine.

# CXC. THE CONSTITUTION OF EQUOL.

By GUY FREDERIC MARRIAN AND DESMOND BEALL.

*From The Department of Biochemistry, University of Toronto.*

*(Received April 17th, 1935.)*

MARRIAN AND HASLEWOOD [1932], while endeavouring to isolate oestrone from a mare's urine extract supplied by Schering-Kahlbaum, A. G., isolated a new non-oestrogenic, optically active compound of the formula  $C_{15}H_{14}O_3$ . It was found that two of the oxygen atoms were present as hydroxyl groups and since the third oxygen atom failed to show reactivity, even as a carbonyl group, it was suggested that it was present in a cyclic ether linkage. Subsequent efforts to obtain further quantities of material for a more detailed chemical examination from extracts from other sources were unsuccessful. The present authors were therefore confronted with the problem of obtaining large amounts of equol and of discovering an explanation for its irregular appearance in mare's urine extracts.

During the summer of 1934 application of the somewhat lengthy isolation process used by Marrian and Haslewood gave regular yields of equol from the toluene extracts of pregnant mare's urine. Subsequently the isolation was considerably simplified by the discovery that equol could be directly crystallised by chloroform from the unpurified ether-soluble phenolic fraction of the toluene extract. Using this simplified process equol was also isolated in appreciable amounts from the urine of stallions and non-pregnant mares. Therefore its excretion is quite unspecific for pregnancy, and since large amounts were found in the urine of non-pregnant mares, there seems to be no reason to associate its presence in urine with the presence of large amounts of the oestrogenic hormones. During the autumn the amounts of equol isolated from urine extracts steadily decreased and in the winter months it was not possible to isolate it at all. So far as can be determined, no dietary factor was the cause of this variation and at present it is impossible to say whether this apparent seasonal fluctuation is fortuitous or not.

Preliminary experiments (unpublished) by Marrian and Haslewood showed that equol dimethyl ether was remarkably resistant to oxidation by alkaline permanganate whereas equol was readily attacked by potash fusion yielding resorcinol. The latter method of decomposition was therefore resorted to by the present authors in obtaining evidence on the structure of the compound. In the first instance a mild potash fusion of equol yielded  $\beta$ -resorecylic acid (2:4-dihydroxybenzoic acid), resorcinol and a phenol  $C_{15}H_{14-16}O_3$  (isolated as its benzoate and subsequently hydrolysed). Since  $\beta$ -resorecylic acid is readily decarboxylated by potash fusion it is probable that resorcinol was formed indirectly from the former. The benzoate of the  $C_{15}$  phenol was found, on analysis, to contain 3 benzoyl groups, showing that the fusion had introduced a third hydroxyl group into the molecule. Methylation of the phenol with diazomethane yielded a dimethyl ether which gave a strongly positive Millon reaction indicating a free phenolic group.

Since it is well known that a phenolic hydroxyl group in the *o*-position to a side chain will not methylate with diazomethane, it seems probable that one

hydroxyl must occupy such a position. Further, the fact that equol on treatment with diazomethane yields the same dimethyl ether as with dimethyl sulphate indicates that it is the hydroxyl group introduced by the potash fusion which occupies the *o*-position to a side-chain.

Potash fusion of compounds in which an oxygen atom is linked directly to two aromatic rings yields products containing two new phenolic hydroxyl groups. Thus xanthone yields 2:2-dihydroxybenzophenone [Richter, 1883]; diphenylene oxide yields 2:2'-dihydroxydiphenyl [Kraemer and Weissgerber, 1901]; thyronine yields quinol and *p*-hydroxybenzoic acid [Harington, 1926]. On the other hand potash fusion of 1:2:3:4-tetrahydrodiphenylene oxide yields 2-hydroxydiphenyl [Hönigschmid, 1901], whilst decomposition of 3-phenylcoumarane with alcoholic potash at 200° yields  $\alpha$ -(2-hydroxyphenyl) phenylethylene [Stoermer and Kippe, 1903]. It therefore seemed probable that the new hydroxyl group introduced was formed by the opening of an oxygen linkage between an aromatic ring and an aliphatic carbon atom.

On the basis of this the partial formula (I) could be constructed for equol, and since the residue ( $C_7H_{10}O$ ) must contain an aromatic ring carrying the second phenolic hydroxyl group, the formula could be extended to (II).

A second potash fusion under more vigorous conditions was then carried out in order to ascertain if possible the nature of the second aromatic ring. The following products were isolated: resorcinol, *p*-hydroxybenzoic acid and *p*-ethylphenol. The two latter compounds were clearly formed from the second aromatic ring of equol. Since the latter contains only fifteen carbon atoms and since the partial formula (II) accounts for eight of them, it follows that the ethyl group of the *p*-ethylphenol must represent two carbon atoms of the aliphatic part of the molecule joining the two aromatic rings. Either carbon atom (*a*) or (*b*) of formula (II) must therefore be the  $\beta$ -carbon atom of the *p*-ethylphenol. In the

first case, formula (III) or (IV), in the second case formula (V) or (VI) must represent equol. Of these possibilities (VI) can almost certainly be excluded since it does not account for the formation of  $\beta$ -resorcylic acid and *p*-ethylphenol by potash fusion. Equol must therefore be 7-hydroxy-2-(4'-hydroxyphenyl)-chromane (III), 7-hydroxy-3-(4'-hydroxyphenyl)chromane (V), or 6-hydroxy-2-(4'-hydroxybenzyl)coumarane (IV).

#### EXPERIMENTAL.

##### *Mild potash fusion of equol.*

2 g. of equol were intimately mixed with 20 g. of finely powdered KOH and heated in a silver crucible to 210–240° for 30 minutes. After cooling, the melt was dissolved in water, the resulting solution saturated with carbon dioxide and extracted with ether. The ethereal solution after drying over calcium chloride was evaporated to dryness and the residue was distilled at 100°/0.02 mm. for several days. The sublimate consisted of 0.16 g. of a white crystalline substance (A) and 0.49 g. of a colourless "glass" (B).

(A) gave a positive fluorescein test and a slate-purple colour with aqueous ferric chloride. After one crystallisation from benzene it melted at 108–109°. Mixed with an authentic specimen of resorcinol (M.P. 110–111°), the M.P. was 109–111°. On nitration in the cold with a mixture of sulphuric and nitric acids, and recrystallisation of the product from dilute alcohol nitroresorcinol, M.P. 176–177° (not depressed by admixture with an authentic sample) was obtained.

Since (B) could not be crystallised it was benzoylated by the Schotten-Baumann method. The product after repeated crystallisations from ethyl alcohol melted at 133–134°.

(Found: C, 77.49, 77.21, 77.36; H, 5.60, 5.79, 5.78 %.  $C_{15}H_{11}(O.CO.C_6H_5)_3$  requires C, 77.95; H, 4.73 %.  $C_{15}H_{13}(O.CO.C_6H_5)_3$  requires C, 77.67; H, 5.07 %.)

0.1225 g. of the benzoate was heated to boiling with 10 ml. of 10 % alcoholic KOH. The mixture was then evaporated to dryness under a stream of carbon dioxide, and the dry residue extracted with ether. The ethereal solution was evaporated and the residue distilled at 140–150°/0.02 mm. for 5 hours. The sublimate was a clear, hard, slightly yellow glass and weighed 40.9 mg. After long standing the regenerated phenol (B) crystallised and melted at 136–137° with preliminary sintering at 130°.

(Found: C, 74.26, 74.14; H, 6.26, 6.61 %.  $C_{15}H_{14}O_3$  requires C, 74.35; H, 5.83 %.)

33.3 mg. of the phenol (B) were methylated with diazomethane in dry ether. The product was purified by sublimation at 100–110°/0.03 mm. After long standing the sublimate crystallised and melted at 66.5–69° with preliminary sintering at 60°. The methylated product gave a strongly positive Millon reaction.

(Found: C, 75.50, 75.37; H, 7.25, 7.23 %;  $CH_3O$ , 22.74, 22.50 %. Mol. wt. 249, 250, 273.  $C_{15}H_{12}O(OCH_3)_2$  requires C, 75.52; H, 6.72;  $CH_3O$ , 22.97 %. Mol. wt. 270.)

The aqueous phase from the solution saturated with carbon dioxide, from which the phenols had been extracted, was acidified with hydrochloric acid and extracted with ether. The ethereal solution after drying over calcium chloride was evaporated to dryness and the residue was distilled at 110°/0.02 mm. for 20 hours. 0.048 g. of a white crystalline sublimate was obtained. This material was purified by washing with cold benzene, recrystallisation from water and finally resubliming at 110°/0.02 mm. It melted with decomposition and evolution

of gas at 198°, and gave an intense purple colour with ferric chloride in aqueous solution. Mixed with an authentic specimen of  $\beta$ -resorcylic acid (M.P. 196°, evolution of gas) which had been purified by crystallisation from water and sublimation *in vacuo*, it melted at 196° with evolution of gas. The identification of the product as  $\beta$ -resorcylic acid was therefore considered to be complete.

*Drastic potash fusion of equol.*

1.76 g. of equol were heated at 300–320° for 80 minutes with 15 g. of KOH. The reaction product was worked up in the same manner as in the first fusion.

The phenolic fraction on distillation at 90–100°/0.04 mm. yielded 0.447 g. of resorcinol and a nearly colourless oil which on standing crystallised. The latter substance (C) melted at about 40° and boiled at 207°. With ferric chloride in aqueous solution it gave a blue colour. It had a faint cresol-like smell, and on benzylation yielded a benzoate which after two crystallisations from aqueous alcohol melted at 58–61° (unchanged when mixed with an authentic specimen of *p*-ethylphenyl benzoate). (C) was therefore *p*-ethylphenol.

The acidic fraction on sublimation at 140–150°/0.04 mm. yielded a white crystalline substance (D) which after two crystallisations from hot water melted at 208–211°. Mixed with authentic *p*-hydroxybenzoic acid (M.P. 211–213°), the M.P. was 209–213°.

On acetylation with acetic anhydride (D) yielded an acetate which after crystallisation from aqueous alcohol melted at 186–190°. Mixed with an authentic specimen of *p*-acetoxybenzoic acid (M.P. 187–189°), the M.P. was 184–189°. The identification of (D) as *p*-hydroxybenzoic acid was therefore considered to be complete.

SUMMARY.

1. Equol may be isolated directly from the ether-soluble phenolic fraction of toluene extracts of the urine of pregnant and non-pregnant mares and of stallions, by crystallisation from chloroform. Its presence in such extracts is irregular. No explanation for this irregularity can be advanced.

2. From the products of the fusion of equol with potassium hydroxide, the following substances have been isolated: a trihydroxyphenol,  $C_{15}H_{14}O_3$  or  $C_{15}H_{16}O_3$ ; resorcinol,  $\beta$ -resorcylic acid, *p*-ethylphenol, and *p*-hydroxybenzoic acid.

3. On the basis of these decomposition products equol is considered to be 7-hydroxy-2-(4'-hydroxyphenyl)chromane, 7-hydroxy-3-(4'-hydroxyphenyl)chromane, or 6-hydroxy-2-(4'-hydroxybenzyl)coumarane.

The authors wish to express their gratitude to the Connaught Laboratories for supplying the urine extracts used in this work and for a personal grant to one of them (D.B.). They are also indebted to Miss H. Stantial for many of the micro-analyses.

# CXCI. THE ANALYSIS OF CARBOHYDRATES OF THE CELL WALL OF PLANTS.

## I. THE RELATION BETWEEN URONIC ANHYDRIDE CONTENT AND FURFURALDEHYDE YIELD.

BY FREDERICK WALTER NORRIS AND CARL EMIL RESCH.

*From the Department of Industrial Fermentation, University of Birmingham.*

*(Received May 15th, 1935.)*

THIS communication has been planned as the first of several dealing with problems in the analysis of the carbohydrate constituents of the cell wall of plants, with special reference to pectin and the hemicelluloses. Such substances yield on hydrolysis hexoses, pentoses and uronic acids, and the most important reaction employed in their proximate analysis involves distillation with 12 % hydrochloric acid, whereby hexose fractions yield a small quantity of hydroxymethylfurfuraldehyde, pentose and methylpentose fractions yield furfuraldehyde and methylfurfuraldehyde, and similarly the uronic acid fraction yields furfuraldehyde, but in addition undergoes decarboxylation with production of carbon dioxide. The products utilised in this publication are pure uronic acids, or uronic acid derivatives, and the analytical complications due to the presence of hexoses and methylpentoses do not arise.

In order, then, to determine the amount of the separate constituents present in any particular cell wall substance, it is necessary to determine, on distillation with 12 % hydrochloric acid:

- (i) The total carbon dioxide produced.
- (ii) The total furfuraldehyde produced.
- (iii) The total methylfurfuraldehyde produced (if methylpentoses are present).

In order to calculate the final analysis certain data must be accurately known:

- (i) The normal percentage yield of carbon dioxide from the uronic acid.
- (ii) The normal percentage yield of furfuraldehyde from the uronic acid.
- (iii) The normal percentage yield of furfuraldehyde from the pentose.
- (iv) The normal percentage yield of methylfurfuraldehyde from the methylpentose.
- (v) The effect of each or all of the above-mentioned constituents, and of hexoses, if present, on the normal percentage yields enumerated.

The relation between uronic acid content and carbon dioxide yield would appear to be the only factor which is known with absolute accuracy. Fortunately the yield of carbon dioxide appears to be theoretical, although it may be mentioned that in dealing with pure uronic acids the evaluation by carbon dioxide determination is usually very slightly lower than that obtained by direct titration. However, the method is not an empirical one and the difficulties have been entirely experimental. It is now safe to say that the carbon dioxide produced on distillation with 12 % hydrochloric acid can be accurately estimated and the uronic acid content calculated directly.

The literature dealing with the production of furfuraldehyde from pentoses and pentosans is extremely voluminous and it is unnecessary to discuss the history of the adaptation of the method to quantitative estimation. It is sufficient to say that the use of phloroglucinol as a precipitant for the distilled furfuraldehyde is still probably the most satisfactory way of estimating the latter and that the publications of Tollens and his co-workers, particularly Kröber [1901], comprise the most complete accounts of the method. In the present communication the methods laid down by these workers have been followed with very little modification, and Kröber's tables have been used for purposes of calculation.

The primary object in publishing this communication is to draw the attention of chemists working in this field to a fatal misconception of the yield of furfuraldehyde from uronic acids which has arisen in recent years. This appears to be due to the acceptance of statements made by Nanji, Paton and Ling [1925], who themselves appear to have misread earlier publications by Lefevre and Tollens [1907]. Thus, the former state that the yield of furfuraldehyde from uronic acid is 31 % of the theoretical and that galacturonic anhydride units yield 16.66 % of their weight of furfuraldehyde. It is wellnigh impossible to reconcile these statements with a correct interpretation of the results of Lefevre and Tollens, who employed glycuronic lactone and derivatives of glycuronic acid, such as euxanthic acid, as reference substances and clearly demonstrated that the weight of furfuraldehyde phloroglucide produced corresponded to one-third of the weight of glycuronic anhydride present. A recalculation of their results, involving merely the substitution of the weight of furfuraldehyde for that of the precipitate by means of Kröber's tables, showed that as an average of eleven determinations on four different products, the furfuraldehyde yield was 18.73 % of the weight of glycuronic anhydride, or that glycuronic anhydride was given by furfuraldehyde  $\times 5.34$ . The data of Lefevre and Tollens therefore showed that the yield of furfuraldehyde from glycuronic anhydride was 34.34 % of theory.

Incidental references to the subject by Ehrlich and Schubert [1929] in which experimental results of the furfuraldehyde yield from galacturonic acid are given, coupled with our own present findings, fully confirm that the original factors of Lefevre and Tollens are more correct than those of Nanji *et al.* [1925].

## EXPERIMENTAL.

### *Determination of uronic acids by decarboxylation.*

The most satisfactory method for this determination is that employed by Dickson *et al.* [1930]. The decomposition of the material is effected by means of 12 % hydrochloric acid contained in a flask fitted with a reflux condenser, to which is attached a trap and a small Büchner flask carrying a Truog tower. The reaction flask is also connected on the other side to a train of wash-bottles, towers and U-tubes containing 50 % caustic potash solution, soda-lime, calcium chloride *etc.*, in order that the stream of air which is drawn through the entire apparatus may be free from carbon dioxide. On heating the reaction mixture to 140–145°, the evolved carbon dioxide is drawn through a known volume of standard barium hydroxide contained in the Truog tower. When decomposition is complete, the carbon dioxide produced is estimated by back-titration with standard acid, using phenolphthalein as indicator.

Certain precautions have been found necessary if satisfactory yields of carbon dioxide are to be obtained. Prior to the initiation of the decarboxylation it is essential to ensure that all carbon dioxide has been swept out of the apparatus by means of the current of carbon dioxide-free air. Carbon dioxide is frequently adsorbed by the calcium chloride used to scrub the air before it passes into the reaction flask. With regard to the Truog tower, a definite technique must be

adopted in adding the standard barium hydroxide, and we have found it desirable to fit a 30 ml. cylindrical dropping funnel to the top of the tower. This in turn is fitted with a soda-lime tube and a second glass tube bearing a small piece of pressure-tubing and a screw clip. The funnel is previously filled with carbon dioxide-free air, and standard barium hydroxide is added from an automatic pipette whereby contamination with carbon dioxide is entirely obviated. At the commencement of the actual decarboxylation, the baryta is allowed to run slowly down the tower, and it is advisable always to ensure that some of the baryta falls into the flask which carries the tower. Whilst the baryta is slowly flowing into the tower, the temperature of the glycerol-bath which carries the reaction flask is slowly raised, the current of air being regulated as necessary. The temperature of the glycerol-bath must be maintained at 140–145°. We have found that the minimum time required for completion of the reaction is 5 hours, but a longer period is frequently necessary.

From time to time blank determinations have been carried out in order to keep a satisfactory check on the apparatus, but always the correction has proved negligible. On actual trial with pure uronic acids the apparatus has given results which differ from the theoretical only by the same negligible margin.

The following reference substances were used for the purpose of the present paper:

(1) *Galacturonic acid monohydrate*,  $C_6H_{10}O_7 \cdot H_2O$ . This product was prepared by synthesis from galactose and the only impurity present in the three samples A, B and C was water. Further drying was not attempted owing to possible decomposition of the samples and the actual content of galacturonic acid was determined by estimation of carbon dioxide on decomposition with 12 % hydrochloric acid or by direct titration using phenolphthalein. The theoretical yield of carbon dioxide from galacturonic acid monohydrate is 20.76 %.

(2) *Pectolic acid*. This product was employed since it is an example of a polygalacturonic acid. It was prepared by Ehrlich and Schubert [1929] and Ehrlich and Guttman [1933] by partial hydrolysis of pectin with 5 % hydrochloric acid, and their methods were followed closely by us. Ehrlich called the product "Pektolsäure", which we have translated as pectolic acid, and according to him its constitution may be represented by a four-membered ring consisting solely of galacturonic anhydride units, together with one molecule of water. Its empirical formula is thus  $C_{24}H_{32}O_{24} \cdot H_2O$ . The theoretical yield of carbon dioxide from a substance of this formula is 24.39 %, equivalent to 107.54 % galacturonic acid.

(3) *Euxanthic acid*. The theoretical yield of carbon dioxide from euxanthic acid is 10.43 %, equivalent to 45.7 % glycuronic acid.

The analysis of these reference substances is shown in Table I.

Table I.

Sample	Carbon dioxide % found	Anhydride $C_6H_8O_6$ calc. %	Acid, $C_6H_{10}O_7$ , %		Purity (based on $CO_2$ det.)
			Calc.	Found (titration)	
Galacturonic acid A	19.75	79.00	87.06	87.50	93.13
Galacturonic acid B	20.67	82.68	91.14	91.54	99.56
Galacturonic acid C	20.11	80.44	88.67	88.67	96.87
Pectolic acid	23.64	94.56	104.23	—	97.01
Euxanthic acid	10.43	41.72	45.70	—	100.00

The amount of galacturonic acid C available was small; the figures quoted for this sample are calculated from the results of direct titration only.

*Determination of furfuraldehyde.*

A definite weight of material and 100 ml. of 12 % hydrochloric acid are placed in a flask of 500 ml. capacity connected by a rubber bung to a Liebig's condenser which carries an adaptor for collecting the distillate in a conical flask. The apparatus is set up in duplicate and the reaction flasks are placed side by side in a bath of glycerol, each flask being immersed in the glycerol exactly to the depth of the 100 ml. acid within. The temperature of the bath is raised to 170° and this temperature is closely adhered to throughout the distillation, which proceeds at the same rate in each flask. As soon as the acid reaches boiling-point, 60 ml. of acid are added, and a similar quantity at 20-minute intervals until six additions have been made. The distillation should be complete in 2 hours and the furfuraldehyde is then precipitated as phloroglucide, by the method suggested by Browne [1912]. 11 g. of phloroglucinol are dissolved in 300 ml. of boiling 12 % hydrochloric acid and added to a further 1200 ml. of acid. The solution is allowed to stand for at least a week and is then ready for use after filtration. The phloroglucinol used should be pure and, particularly, free from diresorcinol; in this respect it was found that AnalaR phloroglucinol was preferable.

40 ml. of this filtered solution are added to the distillate, which should then occupy 400 ml., any slight deficiency being made up with 12 % acid. The mixture is allowed to stand overnight and is then filtered through a weighed Jena sintered glass crucible (grade 1 G. 4), washed with 100 ml. of distilled water, dried at 100° for 3 hours and again weighed.

In this manner the yield of furfuraldehyde from each of the reference substances previously described was determined. In order to avoid any complications, the dry weight of the precipitated phloroglucide was taken and read as furfuraldehyde by means of Kröber's tables. For reasons which will be discussed in a later paper, the practice of washing the phloroglucide with hot alcohol adopted in many laboratories appears to be a somewhat questionable procedure, and the use of Kröber's tables for the alcohol-washed precipitate undoubtedly introduces errors. In the present instance, the weight of the precipitate after alcohol treatment was determined but is not recorded.

Table II shows the results of the furfuraldehyde determinations in full and yields of furfuraldehyde are shown as percentages of the uronic anhydride and of uronic acid present in the sample and compared with the theoretical.

In Table III the ratios of uronic acid and anhydride to phloroglucide and furfuraldehyde produced are shown, calculated from the averages of the results recorded in the first two tables.

Table III. *Average ratios of uronic compounds to phloroglucide and furfuraldehyde produced.*

Substance	Ratio of uronic anhydride to		Ratio of uronic acid to	
	Phloroglucide	Furfuraldehyde	Phloroglucide	Furfuraldehyde
Galacturonic acid A	2.38	4.30	2.62	4.75
Galacturonic acid B	2.36	4.29	2.60	4.72
Galacturonic acid C	2.43	4.25	2.69	4.69
Pectolic acid	2.33	4.20	2.56	4.63
Euxanthic acid	2.61	4.66	2.88	5.14

#### DISCUSSION.

The determination of uronic acids by decarboxylation has already been discussed and calls for no further comment. The results of the determinations of furfuraldehyde as shown in Table II raise several interesting points which require comment. Grouping the three samples of galacturonic acid together, and considering, for example, the yield of furfuraldehyde as a percentage of the uronic anhydride present, the average value is 23.38 % and the mean error of the determination is approximately 2 %. This value, in the case of pectolic acid, is 23.83 %, with a similar mean error of experiment. There is no significant difference between the yields of furfuraldehyde from galacturonic acid as such and from the acid in molecular combination, as in pectolic acid. Examination of the figures for euxanthic acid reveals a significant difference from the figures suggested above; in this case the average yield of furfuraldehyde from the glycuronic anhydride present is 21.48 %, with a mean experimental error of 3.8 %. The higher experimental error in this case is probably due to the presence of a preponderating amount of other organic material—euxanthone—in euxanthic acid, and this also may be responsible for the definitely lower yield of furfuraldehyde, compared with that from galacturonic compounds. From the available results, however, it must be concluded that glycuronic acid in organic combination yields a definitely smaller quantity of furfuraldehyde than does galacturonic acid similarly.

It has been indicated previously and we feel it advisable again to emphasise that the furfuraldehyde yields have been based solely on the application of Kröber's tables to the weight of furfuraldehyde phloroglucide obtained. The influence on the final result of such determinations, of variations in apparatus,

technique of distillation and after-treatment of the precipitate is now being studied. The results of this study which should shortly be available may necessitate a slight modification in the figures of Table IV which indicate the

Table IV.

	Galacturonic acid		Glycuronic acid	
	Present finding %	Nanji, Paton and Ling %	Present finding %	Lefevre and Tollens %
Yield of furfuraldehyde:				
Based on uronic anhydride	23.50	16.66	21.48	18.96
Based on uronic acid	21.33	15.11	19.36	17.21
As percentage of theoretical	43.10	30.54	39.37	34.76
Ratio of uronic anhydride to:				
Phloroglucide	2.36	3.32	2.61	2.93
Furfuraldehyde	4.26	6.00	4.66	5.28
Ratio of uronic acid to:				
Phloroglucide	2.60	3.66	2.88	3.23
Furfuraldehyde	4.69	6.61	5.14	5.83

final averages of all the results of the previous tables, and are compared with the corresponding values applied by Nanji, Paton and Ling to galacturonic acid and those found by Lefevre and Tollens in their study of euxanthic acid.

It will be seen that the proposed yields and factors differ considerably from those of Nanji, Paton and Ling and from those of Lefevre and Tollens. On the other hand, they agree very closely with the recent findings of Ehrlich, referred to previously. Ehrlich and co-workers suggest that the ratio of galacturonic acid to phloroglucide is 2.64 : 1, which agrees, well within the limits of experimental error, with our average ratio of 2.60 : 1.

Our higher yields of furfuraldehyde in comparison with those of Lefevre and Tollens would seem to indicate that under our conditions of distillation there is less destruction of furfuraldehyde, or furfuraldehyde-yielding substance. We have, in fact, accumulated some evidence that this is the case when dealing with pure pentoses and for this reason we have found Kröber's tables inapplicable to such sugars. This will be more fully discussed in the succeeding paper, since the present issue remains unaffected, as we have merely used Kröber's tables to deduce weight of furfuraldehyde from that of the phloroglucide.

The values given by Nanji, Paton and Ling are, of course, not experimental, but arose by some misconception of the work of Lefevre and Tollens. The former values are quoted, however, in order to indicate how far their uncritical acceptance has led many workers astray. The well-known six-membered ring formula for pectic acid proposed by Nanji, Paton and Ling and widely accepted in this country and to some extent elsewhere, was deduced by calculation from the erroneous factors. In view of the considerable difference between these and the more correct factors, it is unlikely that the ring formula is now tenable and revision is called for. The erroneous factors have since been employed in studies on pectin, hemicellulose, gums, mucilages, decomposition of straws, *etc.*, and in many cases results will require recalculation, and considerable revision of the original deductions may be necessary.

Some of the subjects mentioned above are already undergoing experimental revision in these laboratories; thus pectin and pectic acid are being re-examined

in the light of the more correct factors, and it is proposed to extend the observations to calcium pectate and its significance in the analysis of pectic substances.

In our view then, many of the experimental results in this particular field will require close scrutiny and the correction to be applied involves more than the mere substitution of the more correct furfuraldehyde/uronic acid factors. The temptation to follow this simple procedure was strong but was resisted since other factors are concerned. It is essential that we should know accurately the influence on the furfuraldehyde yield of pentoses and uronic acids, of hexoses and other organic substances likely to be present in cell wall material. This question has been studied to some extent and is dealt with in a recent paper by Peter *et al.* [1933] in which it is shown that hexoses have a marked influence on furfuraldehyde yield. Until we have many more data on the yield of furfuraldehyde from mixtures of the type commonly met with, it is idle to attempt recalculation. Further it should be stressed that the use of Kröber's tables, except for correlation of phloroglucide and furfuraldehyde, is quite unjustified, as the tables were constructed for pure xylose and arabinose, and not for mixtures containing only a proportion of these sugars.

It is hoped that the work now proceeding will provide at least some of the missing data and that the analysis of pectin and similar carbohydrates may be placed on a firmer basis.

#### SUMMARY.

1. The furfuraldehyde due to pentose material in cell wall substances may be determined by deduction from the total furfuraldehyde yield of that due to uronic acids.

2. The yields of furfuraldehyde phloroglucide and of furfuraldehyde from galacturonic, polygalacturonic and euxanthic acid are given, together with appropriate factors for calculation.

## CXCII. GUANIDINE AND THE PARATHYROID GLANDS.

BY JOHN ADAMSON SAUNDERS.

*From the Department of Physiology and Biochemistry, University of Durham College of Medicine, Newcastle-upon-Tyne.*

*(Received May 16th, 1935.)*

PATON [1916] propounded the theory that parathyroid tetany was due to the accumulation of guanidine in the body on the grounds (1) that the symptoms of tetany could be produced by the injection of guanidine salts and (2) that there was an increased amount of guanidine in the blood stream and in the urine during tetany. Within a few years the theory fell into disfavour chiefly because of criticisms of the chemical methods used [Greenwald, 1919; White, 1927].

The present experiments were carried out to find whether guanidine is present in increased amounts in the blood of dogs in tetany following parathyroidectomy, the method of isolation being one against which such criticisms could not be levelled [Saunders, 1932].

### EXPERIMENTAL.

#### (1) *Blood from parathyroidectomised animals.*

Four dogs and three cats were bled directly from the carotid artery while in tetany following parathyroidectomy. The blood so procured was extracted for guanidine, but no guanidine was obtained.

Because of the very small amounts of guanidine originally found by Burns and Sharpe [1916] and the lack of delicacy of the method used, these negative results could not be regarded as conclusive.

An attempt was therefore made to find if guanidine is removed from the blood stream of a normal dog at a greater rate than from the blood of a dog in parathyroid tetany.

#### (2) *Blood from parathyroidectomised animals injected with guanidine.*

Five dogs, all in tetany after parathyroidectomy, were intravenously injected with guanidine solutions so as to give a concentration of guanidine base of 90 mg. per 100 ml. blood, this dose being the same as that used for the normal dogs previously reported [Saunders, 1934]. Each animal was bled as completely as possible at a certain time after the injection, and the blood so obtained extracted for guanidine. The amounts of guanidine recovered were 2.6, 4.1 and 4.5 mg. per 100 ml. blood when the animals were bled 7 min. after the injection, and a trace and 1.7 mg. per 100 ml. blood from two animals bled after 15 min. With normal animals bled 3-7 min. after injection 1.8-4.6 mg. per 100 ml. blood were recovered, a trace after 10 and 14 min., and none after 15 min.

The amounts found are thus substantially the same as those for normal animals. If after parathyroidectomy the mechanism for destruction of guanidine has been removed [Paton, 1924], then after the injection of a relatively large dose of guanidine it should be possible to isolate much more of the guanidine injected.

If on the other hand parathyroidectomy has resulted in guanidine being produced at an increased rate [Paton, 1924] such that even with the normally efficient mechanism for its removal [Saunders, 1934] guanidine is present in the blood stream at a concentration of 1–2 mg. per 100 ml. [Burns and Sharpe, 1916], then the injection of a relatively large dose of guanidine should again result in a large increase in blood guanidine for some time after the injection.

The present experiments show that after the injection of amounts of guanidine which should give 90 mg. per 100 ml. blood, there is no appreciable difference between the amounts found in the blood stream of normal dogs and the amounts found in the blood stream of dogs in tetany following parathyroidectomy. It is therefore improbable that the parathyroid glands regulate the production or destruction of guanidine.

The effects of the injection of guanidine on the blood pressure and heart rate after parathyroidectomy were slight and variable, differing from those of injection into normal dogs. The amounts of blood obtained on bleeding from the carotid artery were 32–35 ml. per kg. in three cases and 53 ml. per kg. in two cases, these being similar to the values from normal dogs.

The methods and experimental details are identical with those given in the previous paper [1934]. The picrates were recrystallised from water and identified by microscopical appearance, m.p., base-N and picric acid content. The figures were (1) m.p. 321°; (2) base-N 15.0 %, picric acid 79.2 %, m.p. 322°; (3) base-N 14.3 %, picric acid 80.1 %; (5) m.p. 326°. Guanidine picrate has m.p. 317–323°, base-N 14.8 %, picric acid 79.5 %.

#### SUMMARY.

1. No guanidine could be isolated from the blood of animals in tetany after parathyroidectomy.
2. Injected guanidine is removed as quickly from the blood stream of dogs in tetany as from the blood stream of normal dogs.
3. The evidence produced indicates that it is improbable that parathyroid glands regulate either the production or destruction of guanidine.

I am grateful to the Medical Research Council out of whose grant to Prof. Burns the expenses of this work have been defrayed.

My thanks are due to Prof. Burns and to Mr Secker who performed the thyro-parathyroidectomies, and to Prof. Burns for his continued interest and criticism.

## CXCH. STUDIES IN THE BIOCHEMISTRY OF MICRO-ORGANISMS.

### XLVI. *i*-ERYTHRITOL, A METABOLIC PRODUCT OF *PENICILLIUM BREVI-COMPACTUM* DIERCKX AND *P. CYCLOPIUM* WESTLING.

By ALBERT EDWARD OXFORD AND HAROLD RAISTRICK

*From the Division of Biochemistry, London School of Hygiene and  
Tropical Medicine, University of London.*

(Received May 28th, 1935.)

OF the many crystalline sugar alcohols occurring naturally in the plant kingdom, only mannitol has hitherto been isolated as a metabolic product of the lower fungi when grown on synthetic media. This alcohol is a tissue constituent of many, if not most, mould species and is sometimes present in large amounts in the metabolism solution if glucose or certain other simple sugars are supplied as the source of carbon. Sorbitol has only once, and dulcitol has never been isolated from the tissues of the higher fungi, but the tetrahydric alcohol *i*-erythritol ( $\text{CH}_2\text{OH} \cdot \text{CHOH} \cdot \text{CHOH} \cdot \text{CH}_2\text{OH}$ ) is of frequent occurrence in algae and lichens, and has also been isolated, together with mannitol [Zellner, 1910], from the spores of the corn smut *Ustilago maydis*, a micro-fungus parasitic on maize, *Zea Mays*. It might therefore be expected to occur among the metabolic products of moulds grown on synthetic media. The present paper describes the isolation of *i*-erythritol, in small yield, from the mycelia of two different, and not closely related species of *Penicillium*, viz., *P. brevi-compactum* Dierckx and *P. cyclopium* Westling, both grown on synthetic media.

Since *i*-erythritol is very soluble in cold water (more soluble even than mannitol) it is reasonable to expect that when the mycelium contains a little *i*-erythritol, the metabolism solution may contain very much more, and in view of the difficulty of isolating *i*-erythritol from a dilute solution containing both glucose and mannitol, we cannot, at present, give any estimate of the maximum yield of this alcohol when the most suitable mould species is grown under optimum conditions. With each of the species named above, *i*-erythritol was found in the mycelium only when the metabolism solution still contained a considerable amount of unutilised glucose. The metabolism solution of *P. cyclopium*, grown on a glucose+tartrate medium, did however contain both mannitol and *i*-erythritol (the latter in very small amount) when all the glucose had been utilised and when the mycelium appeared to contain no *i*-erythritol at all. We have also shown, in the case of *P. cyclopium* at least, that *i*-erythritol is definitely a product of metabolism of glucose and that the presence of tartaric acid in the medium is not essential for its formation.

#### EXPERIMENTAL.

##### *Isolation of i-erythritol from the mycelium of P. brevi-compactum Dierckx.*

This experiment was a continuation of the work reported in Part XXXIV [Oxford and Raistrick, 1933] when a strain of *P. brevi-compactum* (L.S.H.T.M. Catalogue No. M 3 (1)) was grown on Raulin-Thom medium of the following composition: glucose, 75 g.; tartaric acid, 4 g.; ammonium tartrate, 4 g.;

diammonium hydrogen phosphate, 0.6 g.;  $K_2CO_3$ , 0.6 g.;  $MgCO_3$ , 0.4 g.;  $(NH_4)_2SO_4$ , 0.25 g.;  $ZnSO_4 \cdot 7H_2O$ , 0.07 g.;  $FeSO_4 \cdot 7H_2O$ , 0.07 g.; water to 1500 ml. 105 one-litre flasks, each containing 350 ml. of the above medium, were sterilised, sown and incubated at 24°, and 26 flasks were worked up after 8 days' incubation when about 50 % of the glucose had been metabolised. The resulting mycelium was dried (66 g.), powdered and extracted in a Soxhlet apparatus, first with light petroleum (B.P. 50–60°) for 2 days to remove fats and sterols and then with ether for 2 working days to remove mycophenolic acid. The extraction was then continued for 3 further working days with fresh ether, and at the end of this time it was found that some colourless material (0.2 g.) had separated from the extract, consisting of a number of visibly crystalline aggregates, mixed with a little amorphous material. The crystalline aggregates, separated by hand, had m.p. 90–100°, raised by crystallisation from alcohol-ether and then from alcohol alone to 116–120°, not changed by a further crystallisation from alcohol, from which the material separated in well-formed tetragonal crystals. It was readily soluble in water to give a neutral solution which gave no coloration with  $FeCl_3$ , and the Molisch and Millon reactions both gave negative results. The substance was obviously a polyhydric alcohol, but its m.p. was depressed by admixture with mannitol (m.p. 165°) or with sorbitol (m.p. 110°). A mixed m.p. with an authentic specimen of *i*-erythritol (m.p. 116–120°) showed no depression and the identity of the product with *i*-erythritol was confirmed by elementary analysis. (Found (Schoeller): C, 39.50, 39.50; H, 8.20, 8.14 %.  $C_4H_{10}O_4$  requires C, 39.31; H, 8.25 %.)<sup>1</sup>

It is evident that the statement in the literature that *i*-erythritol is quite insoluble in ether is incorrect. We find that 1 litre of boiling ether dissolves 25 mg. of the alcohol.

A similar procedure carried out on the mycelium of *P. brevi-compactum* (M 3 (1)), produced on the same medium after 11, 15, 22 and 56 days' incubation, yielded no *i*-erythritol in any case. Unfortunately the respective metabolism solutions, after having been worked up for phenolic substances, had been discarded long before the new product had been identified as *i*-erythritol.

A considerable amount of mycelium of another strain of *P. brevi-compactum* (L.S.H.T.M. Catalogue No. P. 75), grown on the same medium until all or nearly all of the glucose had been metabolised, was similarly worked up, but no trace of *i*-erythritol was found. This mycelium did, however, contain mannitol, a fact previously noted by Alsberg and Black [1913] in their biochemical study of another strain of *P. brevi-compactum* freshly isolated from mouldy Italian maize.

#### *Isolation of i-erythritol from the mycelium of P. cyclopium Westling.*

Thom [1930] places this organism among the "Fasciculata" group of *Penicillium* species. Morphologically it is not related to the "*brevi-compactum*" group.

In our first experiments on the metabolism of *P. cyclopium*, the results of which will form the subject of a later communication, 45 flasks, each containing 350 ml. of Raulin-Thom medium (for composition see p. 1599), were sterilised, sown with a spore suspension of *P. cyclopium* (purchased from Baarn, August 1931, L.S.H.T.M. Catalogue No. P. 123), and incubated for 16 days at 24°, at the end of which time the metabolism solution contained only 1 % of glucose. The mycelium was separated, dried and powdered (214 g.). It was first defatted by extraction for 2 working days with light petroleum (B.P. 50–60°) in a Soxhlet apparatus, then extracted with ether for about 14 working days until no more colourless

<sup>1</sup> The analyst also reported that the substance contained about 20 % alkoxyl as determined by the Zeisel method. Erythritol, reduced by HI, yields *sec*butyl iodide, B.P. 119°, which would be partly distilled over under the conditions of the estimation.

solid separated from the extract. This product was purified by crystallisation from alcohol, after which it was treated with water (10 ml.) and a little insoluble amorphous material removed by filtration. The aqueous filtrate was evaporated to dryness in a vacuum desiccator over solid KOH, to yield fine, large crystals of *i*-erythritol (1.5 g.), m.p. 116–120°, not depressed by admixture with authentic *i*-erythritol, m.p. 116–120°. The crystals so obtained were recrystallised from hot dioxan, as coarse needles, m.p. 116–120°. (Found on this specimen (Schoeller): C, 39.76; H, 8.34 %.  $C_4H_{10}O_4$  requires C, 39.31; H, 8.25 %.)

0.2877 g. in 11.0 g.  $H_2O$  depressed the f.p. by 0.422°; hence mol. wt., 115.  $C_4H_{10}O_4$  requires mol. wt., 122. A 3 % aqueous solution of the substance was optically quite inactive.

*Acetyl derivative.* A solution of the mould product, m.p. 116–120° (0.1 g.) in an excess of acetic anhydride containing a few drops of pyridine was boiled for a minute, kept overnight at 34° and then evaporated to dryness in a vacuum desiccator over solid KOH. The product, crystallised from light petroleum (b.p. 80–100°), formed small prisms, m.p. 83–85° alone or mixed with authentic tetra-acetyl-*i*-erythritol, m.p. 83–85°, similarly prepared. (Found, on acetyl derivative of mould product (Schoeller): C, 50.01, 49.89; H, 6.24, 6.08 %.  $C_{12}H_{18}O_8$  requires C, 49.64; H, 6.25 %.)

A little *i*-erythritol and some mannitol were also isolated from the metabolism solution of *P. cyclopium* when grown on Raulin-Thom medium at 24° for 24 days, at which time all the glucose had been metabolised.

*Production of i-erythritol by P. cyclopium on a medium containing glucose as sole source of carbon.*

In the experiments so far described in this paper, the medium used has always contained tartaric acid in addition to glucose. It was obviously of interest to determine whether the 4-carbon alcohol *i*-erythritol is to be regarded as a metabolic product of the 4-carbon acid, tartaric acid, or whether it may be regarded as a metabolic product of glucose. To this end ten one-litre conical flasks, each containing 350 ml. of Czapek-Dox medium of the following composition: glucose, 50 g.;  $NaNO_3$ , 2 g.;  $KH_2PO_4$ , 1 g.;  $MgSO_4 \cdot 7H_2O$ , 0.5 g.; KCl, 0.5 g.;  $FeSO_4 \cdot 7H_2O$ , 0.01 g.; water to 1000 ml., were sterilised, sown with a spore suspension of *P. cyclopium*, and incubated at 24° for 39 days, i.e., until all the glucose had been metabolised. The dried mycelium (32 g.) when exhaustively extracted with ether (after first defatting with light petroleum) yielded a little colourless material, part of which was soluble in water, the aqueous solution yielding 0.14 g. of almost pure *i*-erythritol, m.p. 110–118°, raised by crystallisation from alcohol-ether to 116–120°, alone or mixed with authentic *i*-erythritol.

#### SUMMARY.

*i*-Erythritol has been isolated in small yield from the metabolism of glucose by *Penicillium brevi-compactum* Dierckx and *Penicillium cyclopium* Westling. It occurs both in the mycelium and in the metabolism solution. It is present in the mycelium in the largest amounts in the earlier stages of growth.

## CXCIV. SYNTHESIS OF GLUTATHIONE.

By CHARLES ROBERT HARINGTON AND THOMAS HOBSON MEAD.

*From the Department of Pathological Chemistry, University College  
Hospital Medical School, London.*

*(Received May 31st, 1935.)*

THE cysteine-containing peptide isolated from yeast and detected in various animal tissues by Hopkins [1921], which was named by him glutathione, was first regarded as a dipeptide of glutamic acid and cysteine; evidence in favour of the view that it was  $\gamma$ -glutamylcysteine was apparently provided by the work of Quastel *et al.* [1923] and of Stewart and Tunncliffe [1925]. The possibility that this hypothesis was incorrect was first indicated by the investigations of Hunter and Eagles [1927] who obtained preparations of glutathione from yeast, blood and liver which undoubtedly contained another amino-acid in addition to glutamic acid and cysteine.

A reinvestigation of the problem by Hopkins [1930] led to the discovery of an elegant method for the separation of the peptide from biological extracts in the form of its cuprous mercaptide; in this way it was possible to obtain the material in the crystalline condition and it then became apparent that glutathione was in fact a tripeptide containing glutamic acid, cysteine and glycine. The same conclusion was reached almost simultaneously by Kendall, McKenzie and Mason [1930] who employed a different method for the preparation of the crystalline peptide from yeast.

The results of electrometric titration of crystalline glutathione led Pirie and Pinhey [1930] to the conclusion that the peptide was either  $\gamma$ -glutamylcysteylglycine or  $\gamma$ -glutamylglycylcysteine. The suggestion advanced by Kendall, McKenzie and Mason [1930] that the glycine and cysteine residues were attached through their amino-groups respectively to the  $\alpha$ - and  $\gamma$ -carboxyl groups of the glutamic acid was rendered most improbable by the observation of Hopkins [1930] that prolonged boiling of an aqueous solution of glutathione resulted in the formation of glutamic acid (or  $\alpha$ -pyrrolidonecarboxylic acid) and glycylcysteine anhydride.

It had been shown earlier by Quastel *et al.* [1923], working with impure preparations of glutathione, that oxidation of the peptide with hydrogen peroxide led to a product which on acid hydrolysis yielded succinic acid; this observation was confirmed by Kendall, Mason and McKenzie [1930, 2] for the crystalline peptide and these workers also showed [1930, 1] that oxidation of glutathione with hypobromite or chloramine T led to no scission of peptide linkages but yielded products from which succinic acid could be isolated after acid hydrolysis.

These observations were consistent only with the supposition that the glutamic acid in glutathione was linked through its  $\gamma$ -carboxyl group, the  $\alpha$ -aminocarboxylic grouping being free and therefore exposed to attack by oxidising agents of the type employed. The possibilities for the structure of glutathione were thus reduced to the two suggested by Pirie and Pinhey [1930].

Evidence as to the relative positions occupied by the cysteine and glycine residues in the molecule of glutathione is available from several sources.  
(a) Scission of the molecule with water can be effected at 62° [Kendall, Mason and

McKenzie, 1930, 2] and under these conditions the residue of cysteine and glycine is liberated as a dipeptide and not as an anhydride; condensation of the dipeptide with 2:3:4-trinitrotoluene yields a product from which free glycine can be separated by hydrolysis, indicating that the dipeptide must have been cysteyle-glycine. (b) Condensation of glutathione with ammonium thiocyanate and acetic anhydride yields a bithiohydantoin [Nicolet, 1930]; on further condensation with benzaldehyde and treatment with alkali followed by reacidification this gives benzylidenethiohydantoin; such a result could only be obtained if the glycine residue occupied the terminal position in the molecule. (c) Glutathione is partly hydrolysed by carboxypolypeptidase [Grassmann *et al.*, 1930] with liberation of glycine as the only free amino-acid: this again could only occur if glycine were in the terminal position.

It is clear therefore that so far as analytical evidence is concerned the structure of glutathione as  $\gamma$ -glutamylcysteylglycine is thoroughly established. The description of the final confirmation of this constitution by synthesis is the object of the present paper.

The problem of the synthesis of a peptide with the constitution assigned to glutathione presents two major difficulties. In the first place it is necessary to devise a method of bringing the  $\gamma$ -carboxyl group of glutamic acid into reaction whilst the  $\alpha$ -carboxyl group is protected, and in the second place the great lability of the  $\gamma$ -glutamyl linkage once formed is a serious obstacle in the way of the final removal of acyl and ester groups which are inevitable constituents of the intermediate products of the synthesis. For these reasons the older methods of peptide synthesis are of little help and it was not until the discovery of the benzylcarbonato method by Bergmann and Zervas [1932] that the synthesis of glutathione came within the bounds of possibility. Even this method in its original form however did not provide a solution of all the difficulties, since the removal of the benzylcarbonato residue, according to Bergmann and Zervas, depending as it does on catalytic reduction, could not be effectively carried out with cysteine-containing derivatives.

In the course of some synthetical experiments by one of us (C. R. H.) in conjunction with Dr S. Kishi (to be published later) on the preparation of thyroxine-containing peptides by the method of Bergmann and Zervas, the difficulty was encountered that removal of the benzylcarbonato residue by catalytic reduction was always accompanied by more or less deiodination. In the search for an alternative reducing agent we were first led to try the mixture of a dilute solution of hydriodic acid in acetic acid with red phosphorus successfully applied by Lamb and Robson [1931] to the reduction of  $\alpha$ -benzamidocinnamic acid derivatives. The results of preliminary experiments with this reducing agent encouraged us to seek for a further improvement and we finally found that warming at 45–50° in acetic acid solution with phosphonium iodide afforded a rapid and efficient means of removal of the benzylcarbonato residue, the benzyl group being eliminated as benzyl iodide instead of as toluene in the case of catalytic reduction. In simple cases such as that of benzylcarbonylglycylglycine deacylation could be effected in this manner with a yield of 80 % of the theoretical amount of the dipeptide and even with derivatives of diiodothyronine the yields were quite satisfactory.

An attempt was next made to substitute phosphonium iodide reduction for catalytic hydrogenation in the last stage of the synthesis of glutamine described by Bergmann and Zervas [1933]; treatment of *N*-benzylcarbonylglutamine in acetic acid solution with phosphonium iodide yielded in fact 35 % of the theoretical amount of crystalline glutamine. The success of this experiment encouraged us to hope that the use of phosphonium iodide might also be effective in

the final stages of the synthesis of glutathione and this expectation has been realised.

The actual course of the synthesis was as follows. *N*-Benzylcarbonylcystine [Bergmann and Zervas, 1932] was converted into the acid chloride and the latter coupled with glycine ester; the product on treatment with phosphonium iodide in acetic acid was converted into cysteylglycyl ester (I) which was conveniently isolated as the hydriodide. *N*-Benzylcarbonylglutamic acid was then converted into the anhydride which with sodium methoxide in methyl alcohol yielded the  $\alpha$ -monomethyl ester of *N*-benzylcarbonylglutamic acid [cf. Melville, 1935]; treatment with phosphorus pentachloride converted the latter into the corresponding acid chloride (II) which was coupled with cysteylglycyl ester to give the ester (III).

The ester groups were removed from III by very careful hydrolysis in alkaline aqueous dioxan solution and the resulting acid was treated with phosphonium iodide under the usual conditions. From the reaction mixture there was obtained in small yield the tripeptide IV which proved to be identical in every respect with an authentic sample of glutathione obtained from natural sources.

The results of the present work therefore leave no doubt that naturally occurring glutathione is, as has been supposed,  $\gamma$ -glutamylcysteylglycine.

In view of the work of Stewart and Tunnicliffe [1925] we have thought it of interest to prepare  $\gamma$ -glutamylcysteine with the aid of the better methods which are now available and a description of this synthesis is included in the present paper. The course of the synthesis follows the lines of that of glutathione itself and calls for no detailed comment.

The synthetic material was distinguished by its remarkable acidity, the  $p_{\text{H}}$  of its aqueous solution being about 2.5; in the oxidised form it had  $[\alpha]_{5461} - 120^\circ$  as compared with  $[\alpha]_{5461} - 97.4^\circ$  for the product of Stewart and Tunnicliffe; the behaviour of the oxidised form of our compound on heating differed from that of the peptide described by the latter authors although the final decomposition points of the two products were the same. The behaviour of an amorphous peptide on heating is however of little significance and in view of the satisfactory analytical

results recorded by Stewart and Tunnicliffe and of the fact that the divergence between the specific rotations of their product and ours is not very great, we are inclined to think that these authors did in fact have in their hands a somewhat impure preparation of  $\gamma$ -glutamylcystine.

#### EXPERIMENTAL.

##### *Deacylation of N-benzylcarbonyl compounds with phosphonium iodide.*

(a) *Preparation of glycylglycine.* Benzylcarbonylglycylglycine (0.5 g.) [cf. Bergmann and Zervas, 1932] was dissolved in glacial acetic acid (20 ml.) to which was added phosphonium iodide (0.5 g.); the solution was contained in a flask provided with a reflux condenser and an inlet tube through which was passed a slow stream of dry hydrogen, the issuing gases being passed through saturated aqueous barium hydroxide and the flask being immersed in a water-bath at 45–50°; after 25 min. evolution of carbon dioxide had ceased indicating that the reaction was complete. The solution was evaporated under diminished pressure and the residue taken up in a little water; after neutralisation with ammonia the evaporation was repeated and the residue again taken up in a little water. Addition of alcohol precipitated glycylglycine in colourless plates which were analytically pure. Yield 80 % of the theoretical. (Found: N, 21.1 %.  $C_4H_8O_3N_2$  requires N, 21.2 %.)

(b) *Preparation of glutamine.* The benzyl ester of benzylcarbonylglutamine (3.7 g.) [cf. Bergmann and Zervas, 1933] was dissolved in alcohol (50 ml.) and the solution treated at room temperature with 2*N* sodium hydroxide (5 ml.). After 1 hour the mixture was only faintly alkaline to thymolphthalein; 2*N* hydrochloric acid (5 ml.) was added and the solution evaporated under diminished pressure; the oily residue was taken up in ethyl acetate and the latter extracted with aqueous sodium bicarbonate; careful acidification of the aqueous extract to maximum precipitation yielded an oil which rapidly hardened. (1.7 g.; 61 % of the theoretical.)

The above product was dissolved in acetic acid (17 ml.) and phosphonium iodide (1.5 g.) was added: after 45 min. under the conditions described above a further addition of phosphonium iodide (0.5 g.) was made. Evolution of carbon dioxide ceased after 1.5 hours in all. The solution was evaporated under diminished pressure and the residue taken up in water; the aqueous solution was washed three times with ether, made slightly alkaline with ammonia and concentrated to a low bulk under diminished pressure; addition of alcohol produced a crystalline precipitate which was collected and weighed (0.19 g.), a further crop of 0.13 g. being obtained by working up the mother liquor; the total yield was therefore 35 % of the theoretical. (Found: N (Kjeldahl), 19.6 %.  $C_5H_{10}O_3N_2$  requires N, 19.2 %; on analysis in the van Slyke amino-nitrogen apparatus there was found, after 5 min. shaking, N, 18.6 %.)

##### *Synthesis of glutathione.*

A few of the compounds described below have already been recorded by Bergmann and Zervas; in these cases we give a brief description of the method of preparation which we have found to be most advantageous.

*N-Benzylcarbonylcystyl chloride.* *N*-Benzylcarbonylcystine (11 g.), finely powdered and thoroughly dried, was suspended in anhydrous chloroform (60 ml.); the mixture was cooled in ice and salt and treated in one portion with powdered phosphorus pentachloride (11 g.); on continued shaking with intermittent cooling almost all passed into solution, after which crystallisation of the

chloride set in rapidly. Separation of the chloride was completed by addition of an equal volume of anhydrous ether and keeping in the freezing mixture for a short time; the crystals were then collected on a sintered glass funnel with exclusion of atmospheric moisture and used immediately for the next reaction.

*N-Benzylcarbonylcystylglycine ethyl ester.* The acid chloride prepared as above from 11 g. of *N*-benzylcarbonylcystine, in as finely divided condition as possible, was added in portions with shaking to a solution of glycine ethyl ester (13.5 g.; 50 % excess) in ethyl acetate (200 ml.) at 0°; after keeping overnight at 0° the precipitate was collected, air dried, triturated with water and again collected; it was recrystallised from *n*-propyl alcohol and corresponded in properties with the product described by Bergmann and Zervas [1932]. Yield 11.5 g. or 75 % calculated on the *N*-benzylcarbonylcystine used. (Found: N, 8.0 %.  $C_{30}H_{38}O_{10}N_4S_2$  requires N, 8.3 %.)

*Cysteylglycine ethyl ester hydroiodide.* *N*-Benzylcarbonylcystylglycine ethyl ester (11.5 g.) was dissolved in warm glacial acetic acid (115 ml.); the solution was cooled to 50° and treated with phosphonium iodide (11.5 g.). Reduction was carried out at 45–50° under the usual conditions, evolution of carbon dioxide being complete in 2½ hours at which time very little phosphonium iodide was left in excess. The solution was evaporated under diminished pressure and the residue taken up in a little glacial acetic acid; on inoculation with a previous preparation (obtained by precipitation of the acetic acid solution with anhydrous ether) crystallisation set in rapidly. Separation was completed by addition of anhydrous ether and keeping at 0° for 2 hours; the product was then collected, washed with ether and dried. Yield 95 % of the theoretical.

Cysteylglycine ethyl ester hydroiodide forms long colourless needles from acetic acid, m.p. 115°; it is non-hygroscopic but exceedingly soluble in water; it is readily soluble in alcohol and warm acetic acid but insoluble in organic solvents. (Found: C, 24.9; H, 4.65; N, 8.30; I, 39.2; S, 9.3 %.  $C_7H_{15}O_3N_2IS$  requires C, 25.2; H, 4.5; N, 8.4; I, 38.1; S, 9.5 %.)

*N-Benzylcarbonylglutamic anhydride.* *N*-Benzylcarbonylglutamic acid (45 g.) was covered with freshly distilled acetic anhydride (120 ml.) and the mixture rapidly brought to the boil; boiling was continued for 2 mins. after which the solution was quickly cooled and evaporated as far as possible under diminished pressure on a boiling water-bath. The residue was poured into a beaker, transference being completed with the aid of a little anhydrous chloroform; on cooling and rubbing crystallisation set in and was completed by addition of 2–3 vols. of anhydrous ether. After keeping for a short time in the cold the product was collected, washed with ether and dried; it corresponded in properties with the preparation described by Bergmann and Zervas [1932]. The yield was 88 % of the theoretical.

*α-Methyl N-benzylcarbonylglutamate.* *N*-Benzylcarbonylglutamic anhydride (35.4 g.) was dissolved in warm anhydrous methyl alcohol (200 ml.); the solution was rapidly cooled and treated, before crystallisation set in, with one equivalent of sodium dissolved in methyl alcohol (60 ml.). After 45 min. the solution was evaporated under diminished pressure; the residue was taken up in water and the aqueous solution washed four times with ether. After acidification with dilute hydrochloric acid the solution was again thoroughly extracted with ether; the ethereal extracts were dried over sodium sulphate and evaporated, the residue being transferred to a flat dish which was placed in a vacuum desiccator over phosphoric oxide. Desiccation was continued in this manner for several days with repeated renewal of the drying agent. The ester formed a colourless very viscous oil. (Found: N, 4.75 %.  $C_{14}H_{17}O_6N$  requires N, 4.75 %.)

*$\alpha$ -Methyl N-benzylcarbonylglutamatocysteylglycine ethyl ester (III).* In the preparation of this compound it was found to be desirable to use a large excess of  *$\alpha$ -methyl N-benzylcarbonylglutamate* for the preparation of the acid chloride. In the first experiments coupling between this chloride and cysteylglycine ester was effected in pyridine solution; since however it is convenient to employ cysteylglycine ester hydroiodide rather than the free ester which is not easy to isolate and since pyridine is not a strong enough base completely to liberate the free ester from the hydroiodide, it was advantageous to employ diethylamine to liberate the ester and bind the hydrochloric acid formed during the coupling and to carry out the reaction in an indifferent solvent.

*$\alpha$ -Methyl N-benzylcarbonylglutamate* (17.7 g.) was dissolved in anhydrous ether (52 ml.); the solution was cooled in ice and salt and treated with powdered phosphorus pentachloride (16.2 g.); after shaking with intermittent cooling for 15–20 min. nearly all the phosphorus pentachloride had disappeared. The solution was decanted from excess of phosphorus pentachloride and evaporated under diminished pressure without application of heat and with exclusion of atmospheric moisture; the residue was rubbed up with ligroin, and the crystalline precipitate collected and washed with light petroleum. It was removed from the filter by percolation with three lots of 12 ml. of anhydrous chloroform which left an appreciable amount of impurity undissolved.

In the meantime cysteylglycine ethyl ester hydroiodide (10 g.) was suspended in anhydrous chloroform (75 ml.) and treated with diethylamine (6.2 ml.; 2 mols.); after brief agitation the hydroiodide passed into solution. The clear liquid was cooled in ice and salt and treated gradually with the chloroform solution of the acid chloride prepared as described above; 1 ml. more of diethylamine was introduced towards the end of the addition of acid chloride in order to maintain an alkaline reaction. After 5 hours at room temperature the solution was filtered and the filtrate washed four times with water, once with dilute sulphuric acid and once again with water; it was then dried over sodium sulphate and evaporated under diminished pressure. The residue was taken up in boiling ethyl acetate (150 ml.) and treated with 1–1.5 vols. of light petroleum (B.P. 100–120°); after keeping at 0° for some hours the product was collected, washed with light petroleum and dried. Crude yield 8.4 g. or 58 % calculated on the cysteylglycine ethyl ester hydroiodide employed.

During the various manipulations a certain amount of oxidation of the product to the sparingly soluble disulphide form had occurred; this made purification difficult and the only method of obtaining a satisfactory preparation consisted in the wasteful process of reduction of the crude product with zinc dust followed by precipitation as the cuprous mercaptide [cf. Pirie, 1931]. The crude material (1 g.) was dissolved in hot alcohol (50 ml.); 7.5 ml. of 5*N* sulphuric acid and 2.5 ml. of water were added and the warm solution was shaken with zinc dust for 15 mins.; the solution was then filtered, the filter being washed with 2/3 *N* sulphuric acid in 80 % alcohol. The filtrate and washings were treated at boiling point with an alcoholic suspension of cuprous oxide which was added drop by drop with careful avoidance of excess. The white precipitate was separated on the centrifuge and washed three times with alcohol; it was then suspended in alcohol and decomposed at boiling point with a vigorous stream of hydrogen sulphide. The cuprous sulphide was separated on the centrifuge and washed with alcohol, the washing being added to the first solution from which crystals had already begun to separate; after heating the combined alcoholic liquors to obtain a clear solution an equal volume of water was added and the whole set aside at 0° overnight; next day the crystalline precipitate was collected,

washed with dilute alcohol and dried. Yield 0.55 g. The ester crystallises in fine colourless needles which tend to form spherical aggregates, M.P. 173°. It is somewhat sparingly soluble in alcohol. (Found: C, 52.28, 52.23; H, 6.06, 6.08, N, 8.99, 8.83; S, 6.17, 6.05 %.  $C_{21}H_{23}O_8N_3S$  requires C, 52.2; H, 6.0; N, 8.7; S, 6.6 %.)

*N-Benzylcarbonyl-γ-glutamylcysteylglycine*. The hydrolysis of the above ester offered considerable difficulties; no success was achieved by working in aqueous or aqueous-alcoholic solution and it was not until aqueous dioxan was tried as a medium that a satisfactory preparation of the acid was obtained. The purified ester (4.6 g.) was dissolved with warming in purified dioxan (50 ml.); after addition of thymolphthalein the solution was rapidly titrated with *N* sodium hydroxide until faintly blue (this required almost exactly one equivalent of alkali and corresponded to the SH group); two more equivalents of *N* NaOH were then added and the mixture kept at room temperature for 1½ hours. At the end of this period the sodium hydroxide used was neutralised exactly by addition of dilute hydrochloric acid; the dioxan was then removed by distillation under diminished pressure and the aqueous residue extracted with ethyl acetate. The latter was extracted with aqueous sodium bicarbonate and the aqueous extract, after washing with ether, was acidified; the oil which separated rapidly hardened and was collected, washed with water and dried. Yield 3.8 g. or 90 % of the theoretical.

The crude product formed a colourless granular powder, M.P. 163° (decomp.) after sintering. (Found: N, 9.2 %.  $C_{18}H_{23}O_8N_3S$  requires N, 9.5 %.) 38.9 mg. required 7.9 ml. *N*/50 NaOH to neutralise to methyl red;  $C_{18}H_{23}O_8N_3S$  titrating as a dibasic acid requires 8.8 ml. of *N*/50.

For analysis a small sample was purified through the cuprous mercaptide; after recovery it was obtained from dilute alcohol as colourless needles, M.P. 166° after sintering. (Found: C, 48.3; H, 5.45; N, 9.2 %.  $C_{18}H_{23}O_8N_3S$  requires C, 49.0; H, 5.2; N, 9.5 %.)

*γ-Glutamylcysteylglycine—glutathione*. *N-Benzylcarbonylglutamylcysteylglycine* (3 g. crude) was dissolved in warm glacial acetic acid (30 ml.) and treated with pulverised phosphonium iodide (2.4 g.); the reduction was carried out as usual. During the reaction a sticky precipitate separated on the walls of the flask and tended to coat the phosphonium iodide and render the latter non-reactive; further additions of 2 and 1 g. of phosphonium iodide were therefore made at 70 and 120 min. respectively. After 140 min. in all the acetic acid was decanted and the precipitate rubbed up with a small amount of alcohol into which it passed into solution with decomposition of excess phosphonium iodide; the acetic acid was treated with excess of anhydrous ether and the precipitate separated and taken up in the minimum of alcohol; the combined alcoholic solutions were then again precipitated with anhydrous ether. The crude peptide hydriodide so obtained was rubbed up with ether until granular, separated at the centrifuge and taken up in the minimum of water; 5*N* sodium hydroxide was cautiously added to  $p_H$  2.9 followed by excess of alcohol; the crude peptide was redissolved in a little water and again precipitated with warm acetone to complete removal of iodide. The precipitate was taken up in 0.5*N* sulphuric acid and the filtered solution treated at 50° with a suspension of cuprous oxide; the mercaptide separated with the characteristic silky sheen noted by Hopkins [1930]. The mother liquor was treated with mercuric sulphate to maximum precipitation and the mercury compound separated, washed and decomposed in the usual manner; renewed treatment of the recovered solution with cuprous oxide gave a small further amount of mercaptide.

The combined precipitates of cuprous mercaptide were washed at the centrifuge until free from sulphate (9 washings), suspended in water and decomposed with hydrogen sulphide; the filtrate from the cuprous sulphide was concentrated in a desiccator over phosphoric oxide to a low bulk and left overnight in a desiccator containing sodium hydroxide and a dish of alcohol and evacuated to 300 mm. Next morning the moist, entirely crystalline residue was collected with the aid of alcohol and dried at 56° in a vacuum over phosphoric oxide. Yield 223 mg.

The material so obtained was pure; it could be recrystallised by solution in water and concentration in a desiccator in presence of alcohol as described. It crystallised in colourless prisms and on rapid heating melted sharply at 190° with effervescence but no immediate coloration; this behaviour was precisely similar to those of authentic natural glutathione and of a mixture of the natural and synthetic products. (Found: C, 39.1; H, 5.55; N, 13.75, 13.66; S, 10.12, 10.27.  $C_{10}H_{17}O_6N_3S$  requires C, 39.1; H, 5.5; N, 13.7; S, 10.4 %.)

The synthetic peptide had  $[\alpha]_{5461} -21.0^\circ$  in water ( $c=2$ ; 1 dm. tube). Precisely the same value was found for authentic glutathione under the same conditions. Hopkins [1930] gives  $[\alpha]_{5461} -18.5^\circ$ .

*Iodine titration of synthetic glutathione.* 10 mg. of the synthetic peptide were dissolved in 5 % potassium iodide and treated with 5 ml. of 0.01 *N* iodine solution; the excess of iodine required 1.75 ml. 0.01 *N* thiosulphate. The iodine used in oxidising the SH group therefore amounted to 3.25 ml. of 0.01 *N* (calc. 3.26 ml. 0.01 *N*).

*Rotation of oxidised glutathione.* No values for the rotation of oxidised glutathione prepared from the pure thiol compound appear to be available in the literature; for further identification of the natural and synthetic products therefore the following experiment was carried out. Synthetic glutathione (10 mg.) was dissolved in water (0.335 ml.); to this were added a minute trace of copper sulphate and the theoretical amount of hydrogen peroxide in water (0.165 ml.) to oxidise the glutathione to the disulphide form; a similar experiment was set up with natural glutathione. After 3 hours at room temperature the nitroprusside reaction had disappeared from both solutions; the solution of synthetic oxidised glutathione had  $\alpha_{5461} -1.07^\circ$  in a 0.5 dm. tube, giving  $[\alpha]_{5461} -107^\circ$  and the natural product under the same conditions had  $\alpha_{5461} -1.08$  giving  $[\alpha]_{5461} -108^\circ$ .

*Formation of cystylglycyl anhydride from synthetic glutathione.* A curious property of glutathione discovered by Hopkins [1930] is the ease with which the peptide is decomposed on boiling in aqueous solution with liberation of glutamic acid (largely in the form of  $\alpha$ -pyrrolidonecarboxylic acid) and cystylglycyl anhydride. This observation has been repeated with synthetic glutathione. The synthetic peptide (77 mg.) was oxidised to the disulphide form with the theoretical amount of hydrogen peroxide and the solution (total volume 3 ml.) boiled under reflux for 42 hours: concentration to a low volume on the steam-bath resulted in separation of crystalline material which after collection and drying amounted to 7.8 mg. After recrystallisation from water this formed large colourless needle-shaped crystals, m.p. 261–262° (decomp.). Hopkins [1930] gives m.p. 262°.

#### *Synthesis of $\gamma$ -glutamylcysteine.*

*$\alpha$ -Methyl N-benzylcarbonylglutamatocysteine ethyl ester.* The acid chloride from 15 g. of  $\alpha$ -methyl N-benzylcarbonylglutamate prepared as above was dissolved in chloroform (30 ml.); cystine ethyl ester hydrochloride (7 g.) was suspended in anhydrous chloroform (75 ml.) and treated with diethylamine (7.8 ml.); to the

resulting clear solution of cystine ester the acid chloride was added gradually with shaking and strong cooling; towards the end of the process further diethylamine (1.9 ml.) was added in order to maintain an alkaline reaction. After keeping overnight the solution was washed three times with water, once with dilute sulphuric acid (excess) and once again with water; it was then filtered through a dry paper, dried over sodium sulphate and evaporated under diminished pressure. The oily residue was taken up in a little ethyl acetate and treated gradually with light petroleum (b.p. 100–120°); the precipitate, at first oily, rapidly became hard and granular. Yield 7.2 g. (44 % of the theoretical calculated on the cystine ester hydrochloride).

For purification the crude ester was reduced to the thiol form by treatment with zinc dust in warm dilute alcohol containing sulphuric acid and then precipitated as the cuprous mercaptide. On recovery the compound formed fine colourless needles from dilute alcohol, M.P. 97°. Considerable loss was involved in the purification. (Found: C, 53.3; H, 6.0; N, 6.4; S, 7.5 %.  $C_{19}H_{26}O_7N_2S$  requires C, 53.5; H, 6.1; N, 6.6; S, 7.5 %.)

*N-Benzylcarbonyl- $\gamma$ -glutamylcysteine*. The above ester (2.5 g.; purified) was dissolved in purified dioxan (12.5 ml.); 2 drops of thymolphthalein were added and *N* sodium hydroxide was run in to the first permanent blue colour (6.0 ml. used; theoretical for 1 equiv. 5.9 ml.); 11.8 ml. *N* sodium hydroxide were then added and the mixture kept at room temperature for 1½ hours. After treatment with 2*N* hydrochloric acid equivalent to the total sodium hydroxide used the dioxan was removed by distillation under diminished pressure. The residue was extracted with ethyl acetate and the latter in turn extracted with aqueous sodium bicarbonate; the alkaline solution was washed with ether, acidified and again extracted with ethyl acetate. The ethyl acetate solution was dried over sodium sulphate and evaporated to a low bulk under diminished pressure; addition of light petroleum to the residue caused the acid to separate as an oil which became cheesy but not completely solid. The compound was used for the next reaction without further purification.

*$\gamma$ -Glutamylcysteine*. *N-Benzylcarbonyl- $\gamma$ -glutamylcysteine* (1.8 g.; crude) was dissolved in glacial acetic acid (18 ml.) and reduced as usual with phosphonium iodide (2.45 g. in all: 1.7 g. at beginning and 0.75 g. after 1 hour); the reaction was complete in 2 hours. The solution was then evaporated under diminished pressure and the residue taken up in a little water; after removal of benzyl iodide by extraction with ether the aqueous solution was adjusted to  $p_H$  2.6 (estimated isoelectric point of the peptide) by addition of 5*N* sodium hydroxide. Alcohol was then added but evidently failed to produce complete precipitation; the  $p_H$  was therefore raised to about 3.4 by addition of saturated aqueous sodium acetate when maximum flocculation occurred; precipitation was completed by addition of acetone. The precipitate was separated at the centrifuge, again taken up in a little water and precipitated with alcohol, this process being repeated twice more to remove the last traces of iodine. The product was then purified through its cuprous mercaptide and separated after recovery from the latter in the same way as described for glutathione; it was finally obtained in two crops, the first consisting of well formed prismatic crystals (177 mg.) and the second of crystalline but less pure material (85 mg.). The compound melted with decomposition at 167° after sintering. It possessed very marked acidic properties, having in aqueous solution  $p_H$  about 2.5. (Found: C, 37.6; H, 5.6; N, 11.1, S, 12.6 %.  $C_8H_{14}O_5N_2S$  requires C, 38.4; H, 5.6; N, 11.2; S, 12.8 %.)

*Iodine titration*. The peptide (10 mg.) was dissolved in 5 % potassium iodide (5 ml.) and treated with 0.01*N* iodine solution (5 ml.); the excess of iodine

required 0.6 ml. of 0.01 *N* sodium thiosulphate. The iodine used up therefore amounted to 4.4 ml. of 0.01 *N* as against the theoretical amount of 4.0 ml. 0.01 *N*.

*Rotation of  $\gamma$ -glutamylcysteine and  $\gamma$ -glutamylcystine.*  $\gamma$ -Glutamylcysteine (110 mg.) was dissolved in water (10 ml.); the solution had  $\alpha_{5461} + 0.15^\circ$  in a 1 dm. tube, giving  $[\alpha]_{5461} + 13.6^\circ$ .

9.7 ml. of the above solution, corresponding to 106.7 mg. of the peptide, were then oxidised with the theoretical amount of hydrogen peroxide in presence of a trace of copper sulphate; after 2 hours the nitroprusside reaction had disappeared and the solution had  $\alpha_{5461} - 1.19^\circ$  in a 1 dm. tube, giving  $[\alpha]_{5461} - 120^\circ$  for the disulphide form of the peptide.

*$\gamma$ -Glutamylcystine.* A sample of the oxidised form of the dipeptide was obtained by evaporating the above solution to dryness in a vacuum desiccator, taking up the glassy residue in a little water and precipitating with excess of absolute alcohol. Separated in this way, it formed a non-hygroscopic amorphous powder; the behaviour on heating was curious since the material swelled up the capillary tube at a little over  $100^\circ$  after which no further change occurred until  $187^\circ$  when brisk decomposition set in. (Stewart and Tunnicliffe [1925] give  $187^\circ$  after softening at  $165$ – $170^\circ$  as the melting point of their product.) (Found: N, 10.6 %.  $C_{16}H_{26}O_{10}N_4S_2$  requires N, 11.2 %.)

# CXCV. THE BEHAVIOUR OF *L*-ASCORBIC ACID AND CHEMICALLY RELATED COMPOUNDS IN THE ANIMAL BODY. ANTISCORBUTIC ACTIVITY IN RELATION TO RETENTION BY THE ORGANISM.

By SYLVESTER SOLOMON ZILVA<sup>1</sup>.

*From the Division of Nutrition, Lister Institute, London.*

*(Received May 29th, 1935.)*

ALTHOUGH *L*-ascorbic acid (*L*-xylo-ascorbic acid) is the most active antiscorbutic substance so far known, other chemically related compounds have been shown to possess antiscorbutic activity. Of these *d*-arabo-ascorbic acid (*d*-erythro-3-ketohexonic acid lactone) [Maurer and Schiedt, 1933] possesses about 1/20 [Dalmer and Moll, 1933; Demole, 1934], *L*-rhamno-ascorbic acid (6-methyl-*L*-arabo-3-ketohexonic acid lactone) 1/5 [Reichstein *et al.*, 1935] of the activity of *L*-ascorbic acid. A homologue *L*-gluco-ascorbic acid is 1/40 active [Reichstein, 1934 and private communication]. This compound was tested recently by the writer and, as will be seen from Fig. 1, was found to be endowed approximately

Fig. 1.

+ = Died  
C. = Chloroformed.  
S. = Scurvy.  
S.S. = Slight scurvy.  
N. = Normal.

↓ = Beginning of dosing.  
↓ = Onset of clinical symptoms of scurvy.  
■ ■ ■ = Negative control.

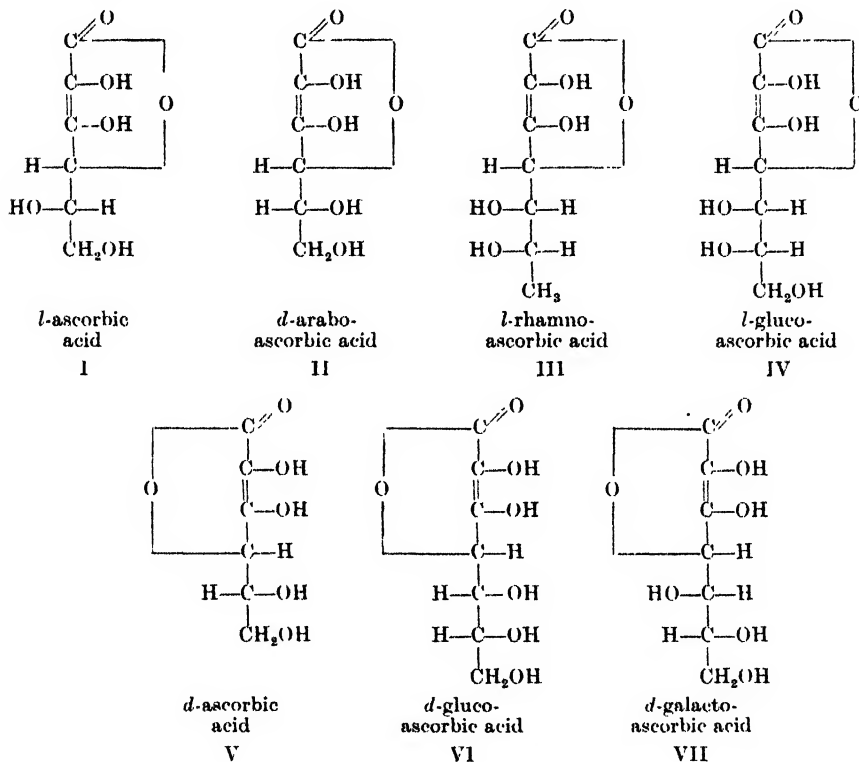

with the activity claimed for it. Unfortunately, owing to scarcity of material, a more accurate assessment was not carried out.

In contradistinction to the above compounds *d*-ascorbic acid failed to show antiscorbutic activity when administered to guinea-pigs on a scorbutic diet in daily doses of 20 mg. [Demole, 1934]. *d*-Gluco-ascorbic acid (*d*-3-ketoglucoheptonofuranolactone) [Ault *et al.*, 1933] and *d*-galacto-ascorbic acid (*d*-3-ketogalactoheptonofuranolactone) [Baird *et al.*, 1934] were found to be totally inactive in daily doses of 10 mg. (Zilva, unpublished results).

<sup>1</sup> Member of the Scientific Staff, Medical Research Council.

It will be seen from formulae I-VII that in all the compounds which show antiscorbutic activity the ring engages the hydroxyl group to the right of the carbon chain and that the opposite is the case with the inactive compounds. In consequence Reichstein [1934] and Haworth [1934] tentatively suggested that such configuration may be a necessary condition of antiscorbutic activity in these substances.

In this communication data are produced which promise to become criteria of value in fathoming the specificity and general mechanism of the biological action of the ascorbic acid group of compounds. The results show that when the animal organism (guinea-pig) is exhausted of *l*-ascorbic acid and the above substances are introduced into the system, the degree of "fixation" by the tissues, especially by those which show "selective fixation" such as the adrenals, anterior lobe of the pituitary, intestine *etc.*, is controlled by the degree of antiscorbutic activity. This fact was reflected further by the excretion of these compounds by the kidney in amounts which varied inversely with the potency.

#### TECHNIQUE.

The purity of the various compounds was assessed by titration with indo phenol. With the exception of a few intraperitoneal and intracardiac injections, the partially neutralised acids were introduced directly into the blood stream through the jugular vein which was layed open under novocaine. After injection the guinea-pigs were placed in a metabolism cage, thus enabling the urine to be

quantitatively collected. Each delivery, except the night urine, was titrated immediately after passing with indophenol at  $p_H$  2.5. Twenty-four hours after injection the animals were killed by stunning and bleeding and the tissues were at once worked up with the utmost speed for analysis. With the exception of the pituitary the material was extracted twice with trichloroacetic acid by grinding with sand and centrifuging, after which the extracts were titrated with  $N/1000$  indophenol at  $p_H$  2.5. The pituitary was removed immediately after killing, placed in a 2 % solution of normal lead acetate for about a minute and then introduced into 0.4 %  $AgNO_3$  and kept in this solution in the dark for 15 minutes. At the end of this time the preparation was washed, fixed with sodium thio-sulphate and preserved in 50 % alcohol. The degree of darkening of the anterior lobe was graded from 0 to + + + +. In the case of the "carcass", the skinned body of the animal from which the brain and the internal organs were removed was passed quickly through a mincing machine, well mixed, and an aliquot portion (20 g.) was extracted with trichloroacetic acid as mentioned above. The guinea-pigs on the mixed diet received a liberal supply of cabbage.

#### DISCUSSION OF RESULTS.

In appraising the experiments it is convenient to consider first the results obtained with the guinea-pigs which received no injection on a scorbutic diet. Such animals, as has been shown by De Caro [1934], are soon depleted of their store of *l*-ascorbic acid. It will be seen that the negative control group lost most of the vitamin contained in the tissues. It is indeed doubtful whether the reduction of the indicator in this case is due mainly to *l*-ascorbic acid. The residual reducing capacity of the tissues of the control animals, whatever its significance, has, however, to be taken into consideration when the figures in the other groups are discussed.

The guinea-pigs which received 50 mg. of *l*-ascorbic acid show a distribution of the injected vitamin amongst the tissues similar to that observed in the case of guinea-pigs kept on a mixed diet. The same "selective fixation" is observed in the adrenals, anterior lobe of the pituitary, intestine and liver as is usually found in all animals whether they obtain the vitamin from a sufficient intake in the food or by synthesis. In addition, with the possible exception of the adrenals and liver, there was no very marked disparity between the quantities of *l*-ascorbic acid found in the respective tissues of the guinea-pigs of the two groups.

Reference must now be made to the animals which received the inactive compounds or rather the compounds which have no antiscorbutic activity in doses so far tested, namely, *d*-gluco-ascorbic acid and *d*-galacto-ascorbic acid. In these cases, considering the limitation of the method, the figures appear to be identical with those of the negative control animals. In other words, neither of these compounds has been "fixed" in the tissues, at least in the reduced form.

This observation becomes arresting when other results in the table disclose the fact that *d*-arabo-ascorbic acid (1/20 active) fills an intermediate position in this respect between the fully active *l*-ascorbic acid and the "inactive" *d*-gluco-ascorbic and *d*-galacto-ascorbic acids. This evidence strongly suggests that the antiscorbutic activity of this class of compounds is correlated with their "fixation" in the tissues.

The weakest link in this chain of evidence is the behaviour of *l*-gluco-ascorbic acid. The quantities of this compound which were "fixed" differed from those of the "inactive" compounds by amounts which fall within the limits of experimental error. It is appropriate, however, to point out at this juncture that

Table I.

Compound injected	Quantity injected mg.	Wt. of animal g.	Scorbutic diet days	Quantity found										Pituitary	Excreted in urine during 24 hours mg.

*l*-gluco-ascorbic acid is claimed to be only 1/40 active and that my test suggests that it may even be less potent. Other results, to be discussed later, support the view of "fixation" by the tissues even in this case.

The contrast between the behaviour of the various compounds is more revealing when the urinary excretions of the acids are compared. Although the greater part of such excretion as took place was completed during approximately the first four hours after injection, it was thought advisable to continue the determination in the urine for twenty-four hours. After this time the amount thus voided became hardly appreciable. It is seen from the figures that the quantity of the compounds passed in the urine is the inverse of the degree of the antiscorbutic activity, a fact which is partly explained by the differential "fixation" of the various acids by the tissues. Moreover, the difference between the amount of *l*-gluco-ascorbic acid excreted in the urine on the one hand and of *d*-gluco-ascorbic acid and *d*-galacto-ascorbic acid on the other appears to fall outside the limit of experimental error, particularly when it is borne in mind that greater accuracy is obtained in titration of these compounds in urine than in most of the tissues discussed here. There is, therefore, an indication, despite its very low activity, that *l*-gluco-ascorbic acid is also "retained" more efficiently than the "inactive" compounds. It must, nevertheless, be acknowledged that this point calls for further examination.

To the writer it seems that the general results justify the assumption that the antiscorbutic activity of these chemically related compounds is connected with their capacity of being "retained" by the tissues of the animal organism. It is obvious that the continuation of this investigation, which is pregnant with a number of possibilities, will shed more light on the matter. The advance of the problem is at the moment slow, being to a great extent dependent upon the continued supply of synthetic material.

With the exception of *l*-ascorbic acid, for which I am indebted to Messrs. Hoffmann La Roche, Ltd., the compounds used in this inquiry were prepared at the University of Birmingham by Prof. W. N. Haworth, Dr E. L. Hirst, Mr J. K. N. Jones and Mr F. Smith for the purpose of assessing the antiscorbutic activity. I should like to express my gratitude to my colleagues for offering me the opportunity of utilising this valuable material in the present work.

# CXCVI. NOTE ON THE KETONIC ACID ANALOGOUS WITH THYROXINE.

By ATTILIO CANZANELLI<sup>1</sup>, RUTH GUILD  
AND CHARLES ROBERT HARINGTON.

*From the Department of Pathological Chemistry, University College Hospital Medical School, London, and the Department of Physiology, Tufts College Medical School, Boston, U.S.A.*

(Received May 29th, 1935.)

THE facts which are at present known regarding the relationship of chemical structure to physiological action in the thyroxine series indicate that the exhibition of typical thyroid-like activity by a compound depends on the presence in its molecule of the thyronine nucleus halogenated at least in the 3:5-positions.

Thus if we take thyroxine as our starting point we find that complete loss of physiological activity follows elimination of one of the benzene rings (3:5-diiodotyrosine), abbreviation of the side chain (thyroxamine) and total elimination of halogen (thyronine); on the other hand elimination of the 3':5'-iodine

Fig. 1. Comparison of effects of thyroxine and its ketonic acid analogue on the metabolism of a dog. The total excess Cals. are 160 or 11 Cals./mg./kg. for the thyroxine and 246 or 3 Cals./mg./kg. for the keto-acid.

<sup>1</sup> On leave of absence from Tufts College Medical School.

atoms only and substitution of iodine by bromine do not involve total loss of activity since 3:5-diiodothyronine and 3:5:3':5'-tetrabromothyronine both possess physiological properties which are qualitatively similar to those of thyroxine.

Since many amino-acids which perform essential metabolic functions can be effectively replaced in the diet by the corresponding keto-acids it appeared of interest to see whether the keto-acid corresponding to thyroxine would exhibit the typical physiological action of the latter.

The synthesis of this keto-acid was effected by well-known reactions and calls for no detailed comment. Its physiological action was examined by determination of its effect on the metabolic rate of a dog under standardised conditions, the methods employed being those described by Canzanelli and Rapport [1933]. The results are shown in Fig. 1 in which the effects of two separate doses of 10 mg./kg. of the keto-acid are compared with the effect of 2 mg./kg. of thyroxine. It will be seen that there is good agreement between the two experiments with the keto-acid and that the total excess metabolism produced amounts to 11 Cals./mg./kg. for thyroxine and to 3 Cals./mg./kg. for the keto-acid.

It is clear therefore that the keto-acid does exhibit the characteristic physiological activity of thyroxine, although in lower degree, and that here again we have an example of the ready interchangeability of amino- and keto-acids in the animal body.

#### EXPERIMENTAL.

##### *Synthesis of 3:5-diiodo-4-(3':5'-diiodo-4'-hydroxyphenoxy)phenylpyruvic acid.*

*Azlactone from acetylglucine and 3:5-diiodo-4-(4'-methoxyphenoxy)benzaldehyde.* An intimate mixture of the aldehyde [Harington and Barger, 1927] (5 g.), acetylglucine (1.22 g.) and freshly fused sodium acetate (5 g.) was treated with freshly distilled acetic anhydride (15 ml.) and the whole was heated for 3 hours on the steam-bath. After cooling the mixture was triturated with water and the yellow solid collected, washed with water and dried. Yield 6.0 g. Recrystallised from glacial acetic acid it formed yellow needles, m.p. 227° (decomp.). (Found: I, 46.2 %;  $C_{18}H_{13}O_4NI_2$  requires I, 45.3 %.)

*3:5-Diiodo-4-(4'-methoxyphenoxy)phenylpyruvic acid.* The above azlactone (9.5 g.) was boiled under reflux for an hour with 30 % aqueous potassium hydroxide (50 ml.). After keeping overnight the somewhat sticky potassium salt was collected and dissolved in water; this solution was saturated with sulphur dioxide as was also the alkaline mother liquor. The two solids thus obtained were collected together, thoroughly washed with ether and dissolved in boiling water (300–400 ml.) with the aid of sodium carbonate; the solution whilst still hot was acidified to Congo red with hydrochloric acid; after cooling the acid was extracted with ether and the ethereal extract dried over sodium sulphate and evaporated. The residue was crystallised from glacial acetic acid from which it separated in needles, m.p. 205° (decomp.). (Found: I, 46.9 %;  $C_{18}H_{12}O_5I_2$  requires I, 47.2 %.)

0.0877 g. required 1.65 ml. 0.1 N NaOH for neutralisation to phenolphthalein; whence mol. wt. = 531.5; calc. mol. wt. = 536.

The acid gave a dark green colour with ferric chloride in alcoholic solution.

*3:5-Diiodo-4-(4'-hydroxyphenoxy)phenylpyruvic acid.* The demethylation of the acid just described offered some difficulty owing to the destructive effect of the demethylating reagent on the keto-acid grouping; success was finally attained by reducing the duration of the reaction to a minimum as follows. The methoxyketo-acid (2.2 g.) was dissolved in 24 ml. of a mixture of equal parts of hydriodic acid (sp. gr. 1.7) and glacial acetic acid; the solution was boiled for

6 min., cooled and diluted to about 100 ml. with water. Free iodine was removed by addition of a little sodium thiosulphate and the solution was extracted five times with ether; the combined ethereal extracts were evaporated without drying and the residue treated with water and a little thiosulphate. The sticky precipitate which separated became partly crystalline on keeping overnight; it was collected, washed with a very little 30 % acetic acid and dried. Yield 1.32 g.

After several recrystallisations from 30 % acetic acid, in which it is easily soluble in the heat, the acid formed colourless plates, m.p. 156° after sintering. (Found: I, 48.3 %;  $C_{15}H_{10}O_5I_2$  requires I, 48.5 %.)

*3:5-Diiodo-4-(3':5'-diiodo-4'-hydroxyphenoxy)phenylpyruvic acid.* The hydroxyphenoxyketo-acid (0.105 g.) was dissolved in a mixture of purified methyl alcohol (1 ml.) and concentrated aqueous ammonia (sp. gr. 0.880; 1 ml.). The solution was cooled in ice and treated, drop by drop with shaking, with the theoretical amount of concentrated solution of iodine in potassium iodide (0.286 ml. of 2.8N); the uptake of iodine was rapid at first but became sluggish after about half had been added. After all the iodine had been introduced the solution was kept for some time in ice until the colour had faded to yellowish-brown; it was then diluted with water, treated with a drop of bisulphite solution and acidified. The precipitate was collected, washed and dissolved in boiling water with the aid of the minimum of sodium carbonate; the sodium salt which separated on cooling was collected and decomposed by solution in hot water followed by acidification; the precipitated acid was finally collected and purified by two crystallisations from acetic acid slightly diluted with water. It formed colourless prisms, m.p. 173°, and gave an intense reaction with nitrous acid and ammonia. (Found: I, 65.0 %;  $C_{15}H_8O_5I_4$  requires I, 65.3 %). The yield was poor.

#### *Metabolic effect of the keto-acid.*

The keto-acid was tested for its effect on the metabolism of an adult female dog living on a constant maintenance diet, the conditions of the experiments being similar to those described by Canzanelli and Rapport [1933], except that the material was administered subcutaneously. The results of two such experiments are shown graphically in Fig. 1 in comparison with the effect on the same animal of a dose of thyroxine. The relative magnitudes of the effects are calculated from the areas enclosed between the respective curves and the line representing the basal metabolic rate of the dog, and it will be seen that the activities of thyroxine and the keto-acid stand in the ratio of 11 : 3.

#### SUMMARY.

The ketonic acid analogous with thyroxine has been synthesised and shown to possess the characteristic physiological activity of the latter compound in lower degree; the ratio of the activities of thyroxine and of the keto-acid is about 11 : 3.

# CXCVII. METABOLISM OF AMINO-ACIDS.

## III. DEAMINATION OF AMINO-ACIDS.

By HANS ADOLF KREBS.

*From the Biochemical Laboratory, Cambridge.*

*(Received May 30th, 1935.)*

NEUBAUER [1909; 1928] and Knoop [1925] showed that the deamination of  $\alpha$ -amino-acids in the mammalian body is accompanied by the oxidation of the  $\alpha$ -C-atom according to the equation

In previous experiments [Krebs, 1933, 1] I have shown that reaction (1) can be conveniently investigated in slices of fresh kidney and liver. It was found that both optical isomerides of the amino-acids are deaminated. In many cases the  $\alpha$ -amino-acids which do not occur naturally—belonging to the *d*-series—are deaminated much more rapidly than the “natural” isomerides.

In this paper it will be shown that the enzymic system catalysing the deamination of the natural amino-acids is different from the system catalysing the deamination of the non-natural optical isomerides. Kidney and liver contain (at least) two different enzymic systems responsible for reaction (1). The two systems differ in many ways. The system deaminating the natural amino-acids is destroyed by drying the tissue; it cannot be extracted; it is inhibited by octyl alcohol and by cyanide. The system deaminating the non-natural amino-acids is not destroyed by drying; it is readily soluble in water and can be extracted from fresh or dried tissue by aqueous solutions; it is not affected by octyl alcohol or by cyanide.

### I. NOMENCLATURE.

The nomenclature used here for the optical isomerides is that introduced by Fischer [1908] and Wohl and Freudenberg [1923]. The amino-acids belonging to the “natural” series are designated “*l*-amino-acids” on account of their spatial configuration, and members of the “non-natural” series are designated “*d*-amino-acids”. The direction of the actual rotation is indicated by (+) or (–).

The system deaminating members of the *l*-series is called “*l*-amino-acid deaminase” and that deaminating members of the *d*-series is called “*d*-amino-acid deaminase”.

No evidence exists showing the occurrence of more than one *d*-amino-acid deaminase. All *d*- $\alpha$ -amino-acids seem to be attacked by the same system. But it is possible that more than one *l*-amino-acid deaminase exists.

### II. METHODS.

The rate of reaction (1) can be measured by determining either the rate of oxygen uptake or the rate of formation of either keto-acid or ammonia. Only certain preparations of the *d*-amino-acid deaminase however show the strictly stoichiometric proportion expected from equation (1) (see Table VI). In tissue

slices, which are necessary for the investigation of the *l*-amino-acid deaminase, other reactions interfere in which oxygen is absorbed and keto-acids are used up or ammonia is either produced or used up. It is impossible to separate the *l*-amino-acid deaminase from these interfering reactions, and therefore the true rate of reaction cannot be measured. The best approximation is obtained by measuring the rate of formation of ammonia, because the ammonia formation and consumption by other reactions is generally small. The rate of ammonia formation after the addition of amino-acid, corrected for the ammonia produced in the absence of amino-acid, gives a measure of the minimum rate of deamination. On the other hand, the oxygen uptake gives the maximum value. Both values have usually been determined but, when the rate of deamination of *l*-amino-acids is mentioned in this paper, it always refers to the rate of ammonia production.

In the case of the *d*-amino-acid deaminase, where equation (1) is usually fulfilled, the oxygen uptake was generally measured manometrically so that the whole course of the reaction could be followed.

The tissue slice technique and the manometric method have been sufficiently described before [Warburg, 1926]. Open manometers and conical flasks with side-bulbs and inner cups were used. The tissue was suspended in phosphate saline [Krebs, 1933, 1] unless otherwise stated. Substrates were neutralised before being added. The gas space was filled with oxygen; the inner cup contained 0.3 ml. *N* NaOH and filter-paper, according to the technique of Dixon and Elliott [1930].

Ammonia was determined by the method of Parnas *et al.* [1924; 1926; 1934]. The amount of ammonia measured was between 0.01 and 0.1 mg. To make alkaline, 3 ml. of a solution of borax-carbonate were used (50 g.  $\text{Na}_2\text{B}_4\text{O}_7$ , 10  $\text{H}_2\text{O}$  + 10 g.  $\text{K}_2\text{CO}_3$  (anhydrous) + 1 ml. 0.1 % thymolphthalein per litre). The solution should be faintly blue ( $p_{\text{H}}$  9.5). Under these conditions, the distillation was always complete if 20 ml. of distillate were collected. The distillate was nesslerised and compared with a standard solution. All the reagents used in experiments on ammonia metabolism were tested regularly to see if they were ammonia-free.

The amount of ammonia is expressed as  $\mu\text{l.}$  in order to simplify direct comparison with oxygen consumption (17 mg.  $\text{NH}_3 = 22,400 \mu\text{l.}$ ). The symbols  $Q_{\text{O}_2}$ ,  $Q_{\text{NH}_3}$  are used for the rate of reaction and mean  $\frac{\mu\text{l.}}{\text{mg. hours}}$ .

### III. EXISTENCE OF TWO DEAMINATING SYSTEMS.

According to Table I, some members of the *d*-series are deaminated by kidney slices much more rapidly than are the corresponding members of the *l*-series.

Table I. *Deamination of d- and l- $\alpha$ -amino-acids by rat kidney slices.*

[From Krebs, *Z. physiol. Chem.* (1933), 216, 204, Tables 5 and 6.] The ammonia formation without amino-acid has been subtracted and therefore  $Q_{\text{NH}_3}$  represents the ammonia formation from the amino-acid. The experimental details are given in the paper quoted.

<i>l</i> -series		<i>d</i> -series	
Amino-acid	$Q_{\text{NH}_3}$	Amino-acid	$Q_{\text{NH}_3}$
<i>l</i> (+) Alanine	2.03	<i>d</i> (-) Alanine	36.5
<i>l</i> (+) Valine	2.53	<i>d</i> (-) Valine	56.5
<i>l</i> (-) Leucine	5.35	<i>d</i> (+) Leucine	33.6
<i>l</i> (+) Glutamic acid	7.73	<i>d</i> (+) Phenylalanine	75.7
<i>l</i> (-) Aspartic acid	13.9	<i>d</i> (+) Aspartic acid	1.26

The existence of two different deaminating systems is shown by the fact that the deamination of *l*-amino-acids is inhibited by conditions which do not affect the deamination of *d*-amino-acids.

(1) *Separation by octyl alcohol.* The substrate used for the *d*-amino-acid deaminase was *d*(-)-valine. The *l*(+)-valine is only slowly deaminated so that it is not suitable for accurate measurements of the activity of the *l*-amino-acid deaminase. *l*(-)-Aspartic acid is the most suitable substrate for this purpose because it shows the highest rate of deamination in the *l*-series. The rate of ammonia formation was estimated as a measure of the rate of deamination. Saturation with octyl alcohol, as shown in Table II, completely inhibits the ammonia formation from *l*(-)-aspartic acid.

Table II. *Influence of octyl alcohol (0.01 ml. in 2 ml. fluid) on the deamination of l(-)-aspartic acid and d(-)-valine.*

(Slices of rat kidney cortex in 2 ml. phosphate saline.  $p_{\text{H}}$  7.4. 37°. 80 mins.)

Substance added (final concentration)	$Q_{\text{O}_2}$		$Q_{\text{NH}_3}$		$Q_{\text{NH}_3}$ (corrected for blank)	
		After addition of octyl alcohol		After addition of octyl alcohol		After addition of octyl alcohol
—	-24.1	- 0.5	2.39	2.11		
<i>l</i> (-)-Aspartic acid <i>M</i> /20	-32.2	- 0.5	9.70	2.22	7.3	0
<i>d</i> (-)-Valine <i>M</i> /20	-41.4	-33	59.2	70	56.8	68

In the absence of octyl alcohol, the  $Q_{\text{NH}_3}$  rises from 2.39 to 9.70 after the addition of aspartic acid, but it remains unchanged in the presence of octyl alcohol. With *d*(-)-valine, however, octyl alcohol does not depress the ammonia formation. Parallel with the effect of octyl alcohol on the ammonia production is its effect on the oxygen uptake. The oxidation of *l*(-)-aspartic acid is inhibited by octyl alcohol, but that of *d*(-)-valine is not.

(2) *Separation by extraction.* 1 g. (wet weight) of the rat kidney that was used in the octyl alcohol experiment was ground with sand in a mortar and extracted with 5 ml. of water. The extract was centrifuged and 0.5 ml. of the supernatant fluid was added to three different flasks containing 2 ml. of phosphate saline with (a) no amino-acid, (b) *M*/20 *l*(-)-aspartic acid, (c) *M*/20 *d*(-)-valine. The other conditions were the same as those given in Table II. The results are shown in Table III.

Table III. *Deamination of l(-)-aspartic acid and d(-)-valine by kidney tissue extract.*

Substance added (final concentration)	Oxygen uptake in 80 mins. ( $\mu$ l.)	Ammonia production in 80 mins. ( $\mu$ l.)
—	36	34
<i>l</i> (-)-Aspartic acid <i>M</i> /20	37	37
<i>d</i> (-)-Valine <i>M</i> /20	462	930

Grinding and extraction have the same effect as the addition of octyl alcohol, *viz.* complete inhibition of the *l*-amino-acid deaminase and no inhibition of the *d*-amino-acid deaminase. By extraction, or by the addition of octyl alcohol, the action of the *d*-amino-acid deaminase is separated from the action of the *l*-amino-acid deaminase. We have thus the possibility of investigating *d*-amino-acid deaminase free from *l*-amino-acid deaminase. The *l*-amino-acid deaminase, on the

other hand, cannot be separated from the *d*-amino-acid deaminase, but it can be investigated separately if "natural" amino-acids are added to kidney or liver slices. In this case, the presence of the *d*-amino-acid deaminase does not interfere, owing to the absence of substrate.

In the following sections, the properties of the *d*- and *l*-deaminases will be described and their interrelations discussed.

#### IV. THE PROPERTIES OF THE *d*-AMINO-ACID DEAMINASE.

(1) *Dry enzyme preparation.* Pig kidney cortex is minced in a "Latapie" mincer within one hour after death. To the minced tissue, 5 vols. of acetone are added. The mixture is thoroughly stirred for 5 mins. and then filtered through a Büchner funnel. The precipitate is dried in a vacuum desiccator over sulphuric acid or phosphorus pentoxide. The dry material is pounded in a mortar. If the powder is kept dry and cool, the activity remains fairly constant for several weeks. After 2 months there was 20–30 % loss in activity.

2 g. of dry powder were shaken for 10 mins. with 80 ml. of water. After being shaken, the fluid was centrifuged. When 2 ml. of the supernatant yellowish fluid (containing 6.2 mg. dry material) were shaken with 0.2 ml. of phosphate buffer ( $p_H$  7.4) at 37° in an atmosphere of oxygen, no oxygen was taken up. When 0.1 ml. of 10 % *dl*-alanine was added, 29  $\mu$ l. of oxygen were taken up in 10 mins. and 59.5  $\mu$ l. in 20 mins.

The activity was not increased by prolonged extraction. Extraction with *M*/150 sodium bicarbonate or with *M*/150  $KH_2PO_4$  gave about the same yield as extraction with water. The insoluble residue was not inactive. When the residue was extracted a second time with 80 ml. of water, an enzyme solution was obtained with about half the activity of the first extract. After 3 or 4 extractions, the insoluble residue was completely inactive. Thus the *d*-amino-acid deaminase is water-soluble.

If slices of kidney cortex are shaken in saline in the presence of oxygen, only small amounts of *d*-amino-acid deaminase pass into the solution. In the absence of oxygen however considerable amounts of the enzyme appear in the solution [Krebs, 1933, 1]. The cells disintegrate more rapidly anaerobically than aerobically and the enzyme can only diffuse out into the solution when the cells are disintegrated.

It is surprising that, although extracting the powder for more than 10 mins. does not increase the activity of the extract, a second extraction for 10 mins. yields a considerable amount of enzyme. This behaviour seems to be due to the fact that, when the extraction is prolonged, inhibiting substances are extracted simultaneously with the enzyme, as shown in the next paragraph.

(2) *Inhibition by tissue substances.* In the previous paper [Krebs, 1933, 1], it was shown that the activity of fresh kidney extracts quickly diminishes: at 37.5°, 30–50 % of the activity was destroyed after 1 hour. Similar observations were made when the dry powder was shaken with amino-acid solution (Table IV and Fig. 1). However, when the powder was extracted for 10 mins. and the extract mixed with amino-acid solution, the activity fell off much more slowly. The stability of the enzyme solution is greater if the insoluble material is removed after brief extraction. The loss of activity is not due to primary instability of the enzyme but to the action of inhibiting substances produced or given off by the tissue material.

The existence of inhibitors can also be demonstrated by diluting the extract (Table IV). The activity of the enzyme is not proportional to the concentration.

Diluted extracts are relatively more active and also the stability of the enzyme increases with dilution. In the example given in Table IV, the loss of activity in the second 40 mins. is 42 % in the undiluted extract and only 15 % in the twice diluted extract.

A direct proof of the presence of inhibiting substances is the inhibition of the enzyme which is observed after the addition of certain tissue extracts. Extracts of rabbit kidney are especially rich in inhibiting substances. 1 ml. of a freshly prepared rabbit kidney extract (1 part of tissue extracted with 40 parts of water) added to 2 ml. of an enzyme preparation from pig kidney (1 part of acetone-dried tissue extracted with 100 parts of water) caused an inhibition of 50 % immediately after the addition, and 80 % after 30 mins. (Table V). Rabbit kidney extract boiled for 10 mins. in a water-bath has no inhibiting power.

A specific inhibition of the enzyme in the intact cell may perhaps account for the results of Abderhalden and Tetzner [1935] who found that rats excrete *d*(-)-alanine unchanged.

Table IV. *Oxidation of dl-alanine in pig kidney.*  
*Comparison of dried powder with extracts from dried powder.*

Extracting fluid *M*/10 phosphate buffer.  $p_H$  7.4.  
Time of extraction 10 mins. *M*/30 *dl*-alanine. 37.5°.  $O_2$ .

Enzyme preparation	Oxygen uptake ( $\mu$ l.)					
	10 mins.	20 mins.	40 mins.	60 mins.	80 mins.	100 mins.
50 mg. acetone-dried powder + 3 ml. phosphate buffer	51	91.5	151	187	209	222
3 ml. extract (corresponding to 50 mg. dry powder)	63	118	210	282	332	364
1.5 ml. extract (as above) + 1.5 ml. phosphate buffer	36	67	129	184	230	271

Table V. *Inhibition of d-amino-acid deaminase by rabbit kidney extract.*

Total volume of experimental fluid 3.5 ml. *M*/30 *dl*-alanine.  
*M*/50 veronal buffer.  $p_H$  8.5. 37.5°.  $O_2$ .

Enzyme solution	Oxygen uptake ( $\mu$ l.)			
	10 mins.	20 mins.	30 mins.	40 mins.
2 ml. pig kidney extract	48	87	119	143
1 ml. rabbit kidney extract	0	1	2	3
2 ml. pig kidney extract + 1 ml. rabbit kidney extract	24	41	54	58.5

The following substances, if added, do not affect the oxidation of *dl*-alanine in extracts of dry powder: pyruvate (*M*/100), ammonium chloride (*M*/100), *l*(+)-alanine (*M*/50), *d*(-)-glutamate (*M*/100), *l*(+)-glutamate.

(3) *Ratio ammonia formation/oxygen uptake.* According to equation (1), 2 mols. of ammonia should be formed when 1 mol. of oxygen is taken up. In order to measure this ratio, conical flasks with two side-bulbs were used [Cremer, 1929]. The main compartment of the flask contained the buffered enzyme solution, side-bulb *a* contained 0.1 ml. of *dl*-alanine (*M*), side-bulb *b* 0.1 ml. of 10 % sulphuric acid. The alanine was added to the enzyme after equilibration and after a reading had been taken; the oxygen uptake was then measured over a certain period. Immediately after the last reading, the acid was mixed with the enzyme in order to stop the reaction. The flask was cooled in ice and the ammonia was determined. Blanks without alanine were done in each experiment. The

blank values for oxygen and ammonia were very small in most enzyme preparations and amounted to only a small percentage of the experimental figures.

A number of results are given in Table VI. The figures are corrected for the blank. In many enzyme preparations, the ratio is equal to the theoretical value within the limits of error. In certain preparations however less ammonia is formed than would be expected from the oxygen uptake. In trout kidney, for instance, the ratio is nearly 1:1. Prof. Keilin tells me that he has found that the oxidation of amino-acids under the action of amino-acid deaminase can be coupled with the oxidation of other substances, such as ethyl alcohol. If a suitable substrate is present, an equipartition of oxygen between amino-acid and the

Tortoise kidney, minced, fresh	10	Phosphate <i>M/100</i>	7.4	60	26	46	1:1.77

other substrate takes place. The ratio ammonia formation/oxygen uptake is thus reduced from 2 to 1. Most enzyme preparations lack a suitable substrate for the coupled reaction or lack the catalyst necessary for the coupling. The ratio ammonia formation/oxygen uptake is in these cases that expected from equation (1). If substrate and catalyst are present, the ratio decreases. Keto-acids are not oxidised by any of the enzyme preparations tested and therefore the decrease in the ratio cannot be due to an oxidation of the amino-acid beyond the stage of the keto-acid.

(4) *Influence of substrate concentration.* 1 g. of acetone-dried pig kidney was extracted with 20 ml. of water by shaking for 10 mins. To 1 ml. of the supernatant fluid, 1 ml. of phosphate buffer ( $p_H$  7.4,  $M/10$ ) and 1 ml. of *d*(-)-valine in various concentrations were added. The oxygen uptake was measured manometrically. Oxygen pressure 1 atmosphere.  $37.5^\circ$ . The results are given in Table VII and Fig. 2.

Table VII. *Influence of the d(-)-valine concentration on the rate of oxidation.*

Concentration of <i>d</i> (-)-valine (mols. per litre)	Oxygen uptake in 20 mins. ( $\mu$ l.)
0.083	47.4
0.025	48.4
0.0083	38.5
0.0025	25.0

The maximum rate is reached when the concentration of the substrate is about  $0.2 M$ . Half the maximum rate occurs at the concentration  $0.002 M$ .

(5) *Influence of the oxygen pressure.* 1 g. of acetone-dried pig kidney was extracted with 20 ml. of water. To 2 ml. of the extract, 0.1 ml. of *dl*-alanine ( $M$ ) and 0.2 ml. of phosphate buffer ( $M/10$ ,  $p_H$  7.4) were added. The oxygen uptake in air ( $37.5^\circ$ ) was  $52.9 \mu$ l. after 30 mins.,  $99.4 \mu$ l. after 60 mins. In oxygen at 1 atmosphere pressure, the oxygen uptake was  $59.1 \mu$ l. after 30 mins.,  $112.0 \mu$ l. after 60 mins. Thus the increase of oxygen pressure from 0.21 atm. to 1 atm. increases the rate of oxidation by 11 %. The shaking was so fast that further increase of its speed did not influence the results.

(6) *Influence of inorganic salts.*  $M/10$  sodium chloride inhibits the activity of an aqueous enzyme solution by about 25 %,  $M$  sodium chloride by 85 %. Stronger concentrations of neutral salts or buffers should therefore be avoided in the investigation of the *d*-amino-acid deaminase.

(7)  $p_H$  optimum. The  $p_H$  curve of the *d*-amino-acid deaminase shows a rather sharp optimum near  $p_H$  8.8 (Table VIII, Figs. 3 and 4). In alkaline solutions the activity of the enzyme diminishes rapidly, whereas near the neutral point the activity remains fairly constant for a considerable period. *dl*-Alanine and *dl*-aspartic acid give similar  $p_H$  curves with the same maximum. Sparingly soluble amino-acids such as cystine or tyrosine are only slowly oxidised at  $p_H$  7.4, but undergo rapid oxidation at  $p_H$  8.5 where the solubility is markedly greater.

(8) *Influence of cyanide.*  $M/10$  cyanide has no influence on the oxidation of alanine by the *d*-amino-acid deaminase ( $p_H$  7.4; concentration of *dl*-alanine  $M$  or  $M/100$ ).

(9) *Influence of narcotics.* Octyl alcohol in saturated solution does not inhibit the *d*-amino-acid deaminase as shown in Table II. Chloroform and toluene are likewise without action.

(10) *Reduction of methylene blue.* Bernheim and Bernheim [1934; 1935] have shown that amino-acids added to kidney extracts reduce methylene blue; they

found that *dl*-leucine reduces methylene blue faster than *dl*-alanine. With *dl*-alanine I find no change in the reduction time as compared with the blank. With *dl*-leucine however a reduction of methylene blue was observed, in accordance with the observation of Bernheim and Bernheim, and ammonia was formed. As enzyme material, an aqueous extract (50 parts of water) of acetone-dried pig kidney (1 part) was used. The enzyme solution and buffer were measured into the main compartment of a conical Warburg flask. The methylene blue (0.1–0.2 ml.) and amino-acid solutions were placed in the side-bulb. The inner cup contained Fieser's [1924]  $Na_2S_2O_4$  solution for absorbing contaminating oxygen. The gas space was filled with nitrogen. After equilibration for 20 mins., the amino-acid and methylene blue were tipped on to the enzyme. The meniscus of the manometer did not change in the following period, showing that no gas was taken up.

This excludes the possibility that the ammonia found was due to the action of contaminating oxygen. A high concentration of methylene blue was used (1 or 2 mg. in each flask). Thus the total amount of ammonia was large enough for accurate determination. The results of the experiment are given in Table IX.

Table IX. *Reduction of methylene blue by dl-leucine.*

Enzyme solution, buffer, $p_H$	Amount of methylene blue added (millimols.)	Final concn. of <i>dl</i> -leucine	Time in mins.	State of methylene blue at the end	NH <sub>3</sub> formed ( $\mu$ l.)
{ 4 ml. kidney extract; 1 ml. <i>M</i> /10 phosphate buffer; $p_H$ 7.4	$2.75 \times 10^{-3}$	0	110	Almost unchanged	30.5
	$2.75 \times 10^{-3}$	<i>M</i> /80	110	Completely colourless	69
{ 5 ml. kidney extract; 1 ml. <i>M</i> /10 phosphate buffer; $p_H$ 7.4	$5.5 \times 10^{-3}$	0	130	Almost unchanged	41
	$5.5 \times 10^{-3}$	<i>M</i> /160	130	Completely colourless	114
{ 5 ml. kidney extract; 0.3 ml. <i>M</i> /10 veronal buffer; $p_H$ 8.5	$5.5 \times 10^{-3}$	0	90	Almost unchanged	41
	$5.5 \times 10^{-3}$	<i>M</i> /160	90	Completely colourless	112

The experiments show that in reaction (1) molecular oxygen can be replaced, in certain cases, by methylene blue. The rate of reaction in the case of leucine is about 50 times slower with methylene blue than with molecular oxygen. The difference is still greater with other amino-acids.

The ammonia formed amounts only to about half the quantity calculated for the amount of methylene blue reduced. This may be explained by partial reduction of methylene blue by keto-acids or other substances present in the enzyme preparations.

(11) *Occurrence in different tissues.* The *d*-amino-acid deaminase occurs in the liver and kidney of all the vertebrates investigated (Tables VI, X). Intestinal wall, spleen, muscle, brain, testis, placenta, chorion, retina, salivary glands, pancreas and heart of the rat do not contain measurable amounts of the enzyme. According to Table X, kidney is about 4 times as active as liver. Acetone-dried

powder of liver and kidney cortex, prepared as described, were extracted with 50 parts of water for 10 mins. To 2 ml. of the supernatant fluid, 0.2 of phosphate buffer (*M*/10,  $p_H$  7.4) and 0.1 ml. of *dl*-alanine (*M*) were added and the results given in Table IX were obtained. In the example given, sheep tissues were about 4 times as active as pig tissue but this is not a regular difference. The activities of sheep and pig tissue are, on the average, of the same order of magnitude.

(12) *Final value of oxygen uptake.* In most preparations the oxygen uptake in the presence of *dl*-alanine corresponds exactly to the theoretical amount calculated on the assumption that only one optical component is oxidised according to equation (1). 4 mols. of *dl*-alanine give rise to the uptake of 1 mol. of oxygen (Table XI and Fig. 5).

Table XI. *Final value of oxygen uptake.*

1 g. of sheep kidney acetone-dried powder extracted with 12.5 ml. of water. The flask contained 2 ml. of enzyme solution and 0.2 ml. of phosphate buffer ( $M/10$ ,  $p_H$  7.4) in the main compartment and 0.20 ml. of *dl*-alanine (0.099  $M$ ) in the side-bulb. The alanine was added after equilibration. 37.5°.  $O_2$ . Theoretical oxygen uptake 111  $\mu$ l.

Fig. 5. Final value of the oxygen uptake of *dl*-alanine.

(13) *Oxidised amino-acids.* 1 g. of acetone-dried pig kidney was shaken for 10 mins. with 40 ml. of water. 2 ml. of extract (containing 6.8 mg. of dry material), 0.2 ml. of  $M$   $NaHCO_3$  and 0.3 ml. of amino-acid solution ( $M/3$  in the case of the *dl*-compounds,  $M/6$  in the case of the *d*-compound) were placed in a manometric flask. If the amino-acid were sparingly soluble, the equivalent amount was added as powder. The  $p_H$  was 8.5 (colorimetrically). The oxygen uptake was measured at 37.5° in oxygen. The inner cup of the flask contained 0.3 ml. of 2  $N$   $NaOH$  and filter-paper. Table XII shows the amino-acids which are deaminated in the presence of *d*-amino-acid deaminase and the rate of oxidation.

Table XII. *Rate of oxidation of various amino-acids in the presence of d-amino-acid deaminase.*

<i>dl</i> -Methionine	139	269	Prepared by Dr Pirie
<i>dl</i> - <i>S</i> -Ethylcysteine	80.5	131	Prepared by Dr Pirie [see Clarke and Inouye, 1931]

No *d*- or *dl*- $\alpha$ -amino-acid has been found—with the exception of *dl*- $\beta$ -hydroxyglutamic acid—which is not attacked by the enzyme. The velocity of the oxidation varies with the chemical structure. Some sulphur-containing amino-acids (*dl*-methionine, *dl*-*S*-ethylcysteine) show the highest rate of oxidation. The simple  $\alpha$ -amino-acids (alanine, valine, leucine) follow next. The oxidation of *dl*- or *d*(- )glutamic acid is slow. *d*(- )Ornithine and *d*(- )lysine have not yet been examined. None of the amino-acids of the *l*-series is oxidised. Inactive glycine is not attacked, whereas phenylglycine, which has an asymmetric C-atom, is oxidised. Amino-acids in which the amino-group is not in the  $\alpha$ -position (*dl*- $\beta$ -alanine, *dl*- $\beta$ -aminobutyric acid, *dl*- $\epsilon$ -amino-*n*-hexanoic acid) are not oxidised, nor are the dipeptides, *dl*-alanylglycine and *dl*-leucylglycine.

The specificity of the enzyme may be used for the determination of the optical configuration of an amino-acid. It may also be used for resolving *dl*-amino-acids and for preparing the *l*-component, thus supplementing Ehrlich's [1906; 1914; 1927] yeast method which yields the *d*-component.

(14) *Occurrence of d-amino-acids.* It seems strange that an enzyme exists that deals specifically with non-natural substrates. But it may be pointed out that  $\alpha$ -amino-acids of the *d*-series have been found occasionally in nature (for reference see Ehrlich [1914], v. Lippmann [1884], Fränkel *et al.* [1923; 1924]). The enzyme described in this paper may be a helpful reagent for tracing

*d*-amino-acids. By adding kidney extract to a solution and measuring the oxygen uptake and ammonia formation, *d*-amino-acids can be detected in the solution.

(15) *Behaviour of the d-amino-acid deaminase in tissue slices.* The experiments dealt with in the preceding paragraphs were carried out on enzyme preparations of tissue, *i.e.* aqueous extracts of dried or fresh tissue. When slices instead of extracts were used as enzyme material, certain properties of the system were found to be different. Unlike the extracted enzyme, the system in the intact cell is inhibited by cyanide and by oxidisable substances.

(a) *Inhibition by cyanide.* The inhibition by cyanide of the *d*-amino-acid deaminase in slices is less than the inhibition of cell respiration. Under the same conditions, the respiration of kidney is inhibited 80 % by  $10^{-3}M$  cyanide and 90 % by  $10^{-2}M$  cyanide. The oxidation of *dl*-alanine is inhibited about 10 % and 40 % by  $10^{-3}$  and  $10^{-2}M$  cyanide respectively (Table XIII).

Table XIII. *Inhibition of d-amino-acid deaminase by HCN in tissue slices.*

The determination of ammonia in the presence of cyanide requires special precautions because cyanide prevents the formation of the yellow colour with Nessler's reagent. If borate buffer is used for liberating ammonia, hydrocyanic acid is found in the distillate. In the presence of cyanide, therefore, stronger alkali must be used. When the amount of cyanide is 3 ml. of  $M/100$ , 2 ml. of 2 *N* NaOH prevent the appearance of significant amounts of cyanide in the distillate.

Similar differences in the inhibition of oxidations in intact cells and in extracts have been found before by Alt [1930] and by Warburg [1931].

In order to explain the fact that cyanide acts differently in slices and in extracts, I follow Warburg and Christian [1931; 1932] and assume that the mechanism of the oxidation of *dl*-alanine is different in slices and in extracts. In extracts, oxygen may react more or less directly with the activated substrate. In slices, oxygen may be prevented from reacting directly with the activated substrate and an activation of oxygen may be necessary; this process is known to be inhibited by cyanide. The view that molecular oxygen does not react in the intact tissue in the same way as in the extract is supported by the finding of inhibiting substances in the tissue which prevent the reaction between oxygen and the amino-acid (Section IV, 2).

(b) *Inhibition by oxidisable substances.* The ammonia production from *dl*-alanine (*M*/50) is inhibited about 50 % by *M*/25 *dl*-lactate (Table XIV). Both alanine and lactate cause a large increase in oxygen uptake if added to kidney.

Table XIV. *Inhibition of ammonia production from dl-alanine by lactate.*

Rat kidney slices in phosphate saline. O <sub>2</sub> .			
Substrate added (final concentration)	Temperature	Q <sub>O<sub>2</sub></sub>	Q <sub>NH<sub>3</sub></sub>
—	25°	— 9.30	1.18
<i>M</i> /75 <i>dl</i> -lactate	25°	— 15.2	0.95
<i>M</i> /30 <i>dl</i> -alanine	25°	— 19.7	8.00
<i>M</i> /75 <i>dl</i> -lactate + <i>M</i> /30 <i>dl</i> -alanine	25°	— 19.1	3.72
—	37.5°	— 27.1	3.00
<i>M</i> /75 <i>dl</i> -lactate	37.5°	— 45.4	2.05
<i>M</i> /30 <i>dl</i> -alanine	37.5°	— 73.5	50.5
<i>M</i> /75 <i>dl</i> -lactate + <i>M</i> /30 <i>dl</i> -alanine	37.5°	— 60.0	25.2
—	21°	— 5.00	—
<i>M</i> /100 <i>dl</i> -lactate	21°	— 11.3	0.34
<i>M</i> /30 <i>dl</i> -alanine	21°	— 16.4	8.14
<i>M</i> /100 <i>dl</i> -lactate + <i>M</i> /30 <i>dl</i> -alanine	21°	— 16.2	5.12

If however the two substances are added together, no summation of the increasing effect on oxygen uptake is observed. The experiments carried out at 25° or 21° are especially convincing since at these temperatures diffusion is certainly not the limiting factor in respiration. The non-summation of the oxygen uptake suggests that the inhibition of ammonia production is due to the fact that, in the presence of lactate, oxygen is partly used for the oxidation of lactate, in other words lactate and alanine compete for the activated oxygen. This would imply that the activation of oxygen is, in its first step, identical for the oxidation of *d*-alanine and *dl*-lactate. This problem will be discussed fully in a later section of this paper.

## V. THE PROPERTIES OF THE *l*-AMINO-ACID DEAMINASE.

(1) *Destruction by drying, extraction or narcotics.* Unlike the *d*-amino-acid deaminase, the *l*-enzyme is destroyed by drying or extracting the ground tissue (see Table III) or by addition of octyl alcohol (see Table II). The *l*-amino-acid deaminase is "bound up with the structure of the living cell". For the investigation of the enzyme therefore tissue slices provide the most suitable material. In slices, the activity of the enzyme remains fairly constant for 2–3 hours.

(2) *Inhibition by cyanide.* The inhibition of the *l*-amino-acid deaminase by cyanide is of the same order of magnitude as the inhibition of the cell respiration, (Table XV). 10<sup>-4</sup> *M* cyanide inhibits the ammonia formation from *l*-aspartic acid by 89 %, 10<sup>-3</sup> *M* inhibits by 94 %. (KCN must be tested for freedom from ammonia which is often present in old solutions.)

In experiments with cyanide, special precautions have to be observed if the inner cup of the manometric flask contains alkali for the absorption of carbon dioxide. Alkali rapidly absorbs hydrocyanic acid. If the concentration of the cyanide is small (10<sup>-4</sup> *M*), all the hydrocyanic acid distills over into the inner cup within a short period and no inhibition ensues. If the concentration of cyanide is high, errors arise because the pressure of the HCN gradually decreases owing to absorption. These errors can be avoided if the inner cup contains an alkali-cyanide mixture, in which the concentration of free HCN is equal to the con-

centration in the experimental fluid. In the presence of HCN therefore the following solutions were used:

Concentration of HCN in the experimental fluid (mol./litre)	Absorbing solution in inner cup
10 <sup>-2</sup>	10 ml. 2 <i>N</i> KCN + 0.2 ml. <i>N</i> KOH
10 <sup>-3</sup>	10 ml. <i>N</i> KCN + 1 ml. <i>N</i> KOH
10 <sup>-4</sup>	5 ml. <i>N</i> KCN + 5 ml. <i>N</i> KOH
10 <sup>-5</sup>	1 ml. <i>N</i> KCN + 10 ml. <i>N</i> KOH

The concentrations of free hydrocyanic acid in the absorbing fluid, calculated from the data of Walker [1889] are roughly the same as in the experimental fluid.

(3) *p<sub>H</sub> optimum curve.* In order to obtain different hydrogen ion concentrations, the concentrations of bicarbonate and free carbon dioxide were varied in the medium (Table XVI). The deamination of *l*-aspartic acid shows an optimum (Fig. 6) at the physiological *p<sub>H</sub>* (7.4). It falls off steeply towards the alkaline side, but slowly towards the acid side. At *p<sub>H</sub>* 6.5, the deamination is still 60 % of the maximum rate. Within the range of *p<sub>H</sub>* occurring physiologically, there is no

considerable difference in the velocity of ammonia formation. If no substrate is added, the ammonia formation changes only slightly with  $p_H$  (see also Patey and Holmes [1930]).

The kidney excretes the more ammonia the more acid the urine or the smaller the concentration of bicarbonate in the blood [Hasselbalch, 1915]. Thus the excretion of ammonia does not run parallel with its formation from amino-acids. From the work of Nash and Benedict [1921] we know that renal veins contain much more (up to 20 times) ammonia than the renal artery. This indicates that normal kidney produces more ammonia than is needed for excretion. It depends on the conditions of the acid-base equilibrium whether the ammonia formed in kidney from amino-acids is excreted in the urine or appears in the venous blood.

(4) *Influence of substrate concentration.*  $M/200$  *l*-aspartic acid gives almost the maximum rate of deamination (Table XVII). At lower concentrations of substrate, the ammonia formation is considerably smaller. It may be noted that the amino-nitrogen concentration of blood plasma lies between  $M/100$  and

(5) *Reduction of methylene blue.* Tissue slices of kidney slowly reduce methylene blue if kept in saline at  $37.5^{\circ}$  in the absence of oxygen. For instance, 3 mg. of methylene blue in 6 ml. saline were reduced by 44 mg. (dry weight) rat kidney slices in 2 hours. Addition of  $M/100$   $l(-)$ aspartic acid did not influence the velocity of reduction nor did it increase ammonia formation. Brilliant cresyl blue is reduced a little more quickly than methylene blue but again aspartic acid has no effect on the rate of ammonia production. It should be emphasised that the non-reduction of these indicators does not prove anything as to the activation or non-activation of the substrate molecule.

Thunberg [1920; 1923] has studied the reduction of methylene blue by a large number of amino-acids, but none except glutamic acid and perhaps alanine gave increased reduction in muscle or nervous tissue. The question whether the reduction of methylene blue in the presence of glutamic acid is accompanied by formation of ammonia was not investigated.

(6) *Separation of the  $l$ -amino-acid deaminase from cell respiration.* The  $l$ -enzyme resembles the general cell respiration as regards sensitivity to drying, extraction, octyl alcohol or hydrocyanic acid. It differs however from most other cellular oxidations as to sensitivity to arsenious oxide. Arsenious oxide strongly inhibits cell respiration [Warburg and Onaka, 1911]; it inhibits particularly the breakdown of the keto-acids formed according to equation (1) [Krebs, 1933, 1, 2]. It does not inhibit the deamination of  $l(-)$ aspartic or  $l(+)$ glutamic acid. In the presence of arsenious oxide therefore keto-acids accumulate in the solution. Aspartic acid yields oxaloacetic and pyruvic acids, glutamic acid yields  $\alpha$ -ketoglutaric acid. The keto-acids can be detected by carboxylase or can be isolated as dinitrophenylhydrazones [Krebs, 1933, 2]. Thus kidney is able to split off the ammonia from  $l(-)$ aspartic and  $l(+)$ glutamic acids according to equation (1) without oxidising the rest of the amino-acid molecule. We may therefore speak of a  $l$ -amino-acid deaminase as an oxidising system different from the other systems in the tissue.

(7) *Inhibition by oxidisable substances.* The deamination of  $l$ -amino-acids is inhibited if substances which are readily oxidised, such as lactate or pyruvate or succinic acid or  $\alpha$ -keto-acids are added. Some examples are given in Table XIX.

Table XIX. *Inhibition of ammonia production from  $l(-)$ aspartic acid by oxidisable substances.*

Rat kidney. Concentration of the substrates  $M/100$ .  $37.5^{\circ}$ .

Substrates added	$Q_{O_2}$	$Q_{NH_3}$
No substrate	- 21.0	1.52
$l(-)$ Aspartic acid	- 37.1	12.6
Pyruvic acid	- 42.2	—
Lactic acid	- 40.9	—
$l(-)$ Aspartic + pyruvic acids	- 39.1	4.56
$l(-)$ Aspartic + $dl$ -lactic acids	- 38.5	4.21
$l(+)$ Glutamic acid	- 41.0	6.03
$\alpha$ -Ketoglutaric acid	- 38.4	0.34
$l(+)$ Glutamic + $\alpha$ -ketoglutaric acids	- 42.0	0.94

Addition of  $M/100$   $dl$ -lactate to  $M/100$   $l(-)$ aspartic acid inhibits ammonia formation by 67 %.  $M/100$  ketoglutaric acid inhibits ammonia production from  $M/100$   $l(+)$ glutamic acid almost completely. Glucose has no appreciable effect on the oxidation of amino-acids.

This inhibition is not due to secondary utilisation of ammonia in the presence of the added substrate since added ammonia disappears very slowly from rat

Table XX. *Utilisation of ammonia in rat kidney in the presence of various substrates.*

Substrate added	mg. tissue	Amount of ammonia ( $\mu$ l.) in 3 ml. of solution		$Q_{\text{NH}_3}$	$Q_{\text{O}_2}$
		Initial	After 80 mins.		
—	8.85	29.2	35.5	+ 0.56	- 26.1
<i>dl</i> -Lactate ( <i>M</i> /100)	10.96	29.2	23.7	- 0.38	- 40.5
Pyruvate ( <i>M</i> /100)	11.69	29.2	24.2	- 0.32	- 41.2
$\alpha$ -Ketoglutaric acid ( <i>M</i> /100)	9.99	29.2	23.5	- 0.43	- 37.2

kidney in the presence of these substrates (Table XX). If the tissue is offered several substrates, they compete for the oxygen available. Each of these substrates increases the  $Q_{\text{O}_2}$  from about 20 to about 40 (37.5°). In the presence of several substrates however no summation of the increasing effect on respiration ensues; the oxygen uptake is again about 40. The constant oxygen uptake, together with the decreased ammonia production observed when a second substrate is added to amino-acids, indicates that the second substrate is oxidised instead of the amino-acid ("sparing action", see also Dickens and Greville [1933]).

In order to ensure that a maximum figure of  $Q_{\text{O}_2}$  is not limited by the rate of the diffusion, some experiments were carried out at 20°, where the velocity of reactions is less and diffusion cannot be a limiting factor. Again no summation was found but there was displacement of amino-acid by other substrates (Table XXI).

Table XXI. *Inhibition of ammonia production from l(+)glutamic acid by  $\alpha$ -ketoglutaric acid at 20°.*

Rat kidney.		
Substrates added ( <i>M</i> /100)	$Q_{\text{O}_2}$	$Q_{\text{NH}_3}$
—	- 3.82	0.36
<i>l</i> (+)Glutamic acid	- 6.68	1.29
$\alpha$ -Ketoglutaric acid	- 6.52	0.23
<i>l</i> (+)Glutamic acid + $\alpha$ -ketoglutaric acid	- 7.50	0.13

I explain the fact that no summation takes place by assuming that the mechanism of activation of molecular oxygen is identical when different substrates are oxidised. But the following experiments make it probable that the activation of the substrate is different in the case of *l*-amino-acids and other substrates. If arsenious oxide ( $10^{-3}$  *M*) is added to kidney, the oxidation of  $\alpha$ -keto-acids is more inhibited than the oxidation of amino-acids. Arsenious oxide therefore can restore the oxidation of amino-acids which was inhibited by the presence of keto-acids (Table XXII). If amino-acids compete with other substrates for oxygen, arsenious oxide shifts the position in favour of the oxidation of amino-acids. The simplest explanation of this effect is the assumption that the activation of amino-acids is less inhibited by arsenic than is the activation of other substrates.

The inhibition of cellular oxidation by arsenious oxide was discovered by Warburg and Onaka [1911]. The experiments of Banga *et al.* [1931] have already suggested that the partial reaction affected is the activation of the substrate (dehydrogenase).

Table XXII. *Influence of As<sub>2</sub>O<sub>3</sub> on oxygen uptake and ammonia production.*

Rat kidney. 25°.

	Substrates added	As <sub>2</sub> O <sub>3</sub> concentration	Q <sub>O<sub>2</sub></sub>	Q <sub>NH<sub>3</sub></sub>
		<i>M</i>		
1.	—	0	— 8.50	0.63
2.	—	10 <sup>-3</sup>	— 2.00	0.75
3.	<i>l</i> (+)Glutamic acid ( <i>M</i> /100) + α-ketoglutaric acid ( <i>M</i> /100)	0	— 18.7	0
4.	<i>l</i> (+)Glutamic acid ( <i>M</i> /100) + α-ketoglutaric acid ( <i>M</i> /100)	10 <sup>-3</sup>	— 3.42	1.13

The inhibition of deamination by lactate described in this paragraph explains why kidney slices may produce less ammonia if suspended in serum than in saline. It may also explain why in perfusion experiments the rate of deamination in kidney was found to be small or negligible [Bornstein and Budelmann, 1930]. Under the conditions of a perfusion experiment, the lactic acid concentration in blood is often unphysiologically high (owing to blood glycolysis, effect of anaesthetics and various other circumstances).

The method of investigating the summation offers the possibility of deciding generally whether the oxidation of various substances in cells involves entirely separate systems for each substrate. Some experiments (Table XXIII) were

Table XXIII. *Oxygen uptake of baker's yeast in the presence of various substrates.*Each flask contained 3 ml. of yeast suspension (4 mg. dry weight) in *M*/20 KH<sub>2</sub>PO<sub>4</sub>. 17°.

Substrate added (final concentration)	Oxygen uptake (μl.)		
	40 mins.	80 mins.	Q <sub>O<sub>2</sub></sub>
---	21	34	— 6.4

Sodium <i>dl</i> -lactate ( <i>M</i> /50)	188	388	— 72.6
Sodium acetate ( <i>M</i> /20)	67	199	— 37.5
Sodium butyrate ( <i>M</i> /20)	62	116	— 21.8
Sodium α-ketoglutarate ( <i>M</i> /50)	164	342	— 62.1
Glucose ( <i>M</i> /20) + sodium <i>dl</i> -lactate ( <i>M</i> /50)	218	435	— 81.5
Glucose ( <i>M</i> /20) + sodium acetate ( <i>M</i> /20)	212	432	— 81.0
Glucose ( <i>M</i> /20) + sodium butyrate ( <i>M</i> /20)	192	402	— 75.2
Glucose ( <i>M</i> /20) + sodium α-ketoglutarate ( <i>M</i> /50)	245	426	— 80.0

carried out with yeast cells. Yeast is a very suitable material since its respiration without substrate is very small and the addition of substrate causes a great increase (more than 1000 %) in the respiration. Suitable substrates of different types are glucose, *dl*-lactate, acetate, butyrate and α-ketoglutarate. Each substrate brings about a large increase in respiration, but no summation ensues when two substrates are added simultaneously. This seems to prove that the systems responsible for the oxidation of various substrates have one component in common, most probably the part which activates the molecular oxygen.

(8) *Occurrence of l-amino-acid deaminase in different tissues.* Kidney cortex shows by far the highest rate of deamination of *l*-amino-acids in all the animals examined (rat, guinea-pig, rabbit, cat, dog, sheep, pig). Table XXIV gives some instances comparing the oxygen uptake and the ammonia production in liver and kidney after the addition of *l*(-)-aspartic acid. In kidney the amino-acid roughly doubles the oxygen uptake and causes a large increase in the ammonia

Table XXIV. *Oxygen uptake and ammonia formation of various tissues in the presence of l(-)aspartic acid.*

production. In liver both changes are only slight. Other amino-acids show similar differences. Since however the amount of liver tissue in the body is (roughly) five times as much as the amount of kidney cortex, the share of the liver in deamination is considerable. Besides, the amino-acids coming from the intestinal tract are at a higher concentration when they reach the liver than when they reach the kidney. It may be therefore that the amino-acids of the food are preferentially deaminated in the liver.

Slight increases in oxygen uptake and ammonia formation are frequently observed if *l*-amino-acids are added to intestinal wall, especially the lower part (caecum) (see also London *et al.* [1934]), although the increase in ammonia formation is only about a tenth of that in kidney. Addition of amino-acid to rat diaphragm does not cause an increase in oxygen uptake or ammonia formation. Minced muscle however shows increased oxygen uptake in the presence of *l*-aspartic acid and *l*(+)-glutamic acid [Needham, 1930]. The rate of oxidation in muscle is very slow and no ammonia is found if these amino-acids are present.

The mouse Crocker tumour and the following rat tissues do not show a measurable increase in ammonia formation if *l*-aspartic acid or *dl*-alanine is added to slices suspended in glucose-containing (0.2 %) saline; brain, retina, spleen, testicle, placenta, chorion, red blood corpuscles, red bone marrow, pancreas, salivary glands, Jensen rat sarcoma.

However, brain and retina have an increased respiration in the presence of glutamic acid. The respiration of brain or retina *in vitro* falls off quickly if no suitable substrate is added. Suitable substrates are carbohydrates (glucose, fructose), lactate and pyruvate. *l*(+)-Glutamic acid is the only amino-acid which I have found capable of maintaining the respiration of brain or retina (Tables XXV and XXVI and Fig. 7). This is in accordance with Quastel and Wheatley's [1932] results. But the solution in which glutamic acid is oxidised does not contain an increased amount of ammonia. Glutamic acid seems to influence the respiration without being deaminated. This phenomenon will be dealt with fully in a subsequent paper.

## VI. CELL STRUCTURE AND ENZYME ACTION.

(1) *Deamination of l-amino-acids in tissue "brei". Effect of dilution.* The main difference between the *d*-amino-acid and *l*-amino-acid deaminases appears to be the behaviour on extraction of the ground tissue. The *d*-amino-acid deaminase can be extracted and the *l*-amino-acid deaminase cannot. This

difference is not merely a difference in solubility since, in the case of the *l*-amino-acid deaminase, both the supernatant fluid and the insoluble residue of the ground tissue are inactive.

The *l*-amino-acid deaminase belongs to the large category of cellular oxidations which are said to be bound up with the structure of the living cell. The bulk of the cell respiration also disappears when the tissue is ground and extracted.

In order to analyse the difference between the two deaminases, the process of extraction was studied in detail. Experiments described in this section show that the enzyme is inactivated, not by grinding and destruction of the cell, but by the dilution of the protoplasm which necessarily accompanies extraction. The extent of the dilution determines the extent of the inactivation. This is true for the *l*-amino-acid deaminase and for the bulk of the cell respiration.

Table XXVII shows some examples of the effect of grinding and dilution on *l*-amino-acid deaminase. For these experiments, kidneys of larger animals were obtained from the slaughter house as soon as possible after the death of the

\* Kidney kept on ice for 3 hours before the experiment.

animal. The cortex was minced in a "Latapie" mincer. To the mashed tissue, one volume of phosphate-saline was added. The mixture was thoroughly shaken in a stoppered measuring cylinder. This suspension of the whole kidney was used for the experiments. It can be conveniently measured with a pipette.

The tissue in this suspension is diluted by one volume. This dilution is unavoidable since the concentrated mince is semi-solid and cannot be saturated with oxygen and with substrate. 0.5 ml. of the suspension (about 60 mg. dry weight) was measured into each Warburg flask and 0.5 ml. of *M*/5 *l*(-)*aspartate* was added. Varying amounts of phosphate-saline were added for further dilution. Thus the flasks contained a constant amount of tissue and amino-acid, but a varying amount of suspension fluid. Controls were carried out without *l*(-)*aspartate*. The gas space was filled with oxygen. The shaking was fast since the oxygen uptake was very large in the concentrated suspensions. In the "brei" that was diluted 4-fold, the rate of ammonia formation from *l*(-)*aspartic acid* is still of the same order of magnitude as it is in slices. With 8- or 16-fold dilution, the deamination is much inhibited, in some experiments almost completely.

(2) *Effect of dilution on respiration of tissue "brei".* Tables XXVIII and XXIX show the effect of dilution on the respiration of kidney "brei". The more

\* The dry weight of kidney cortex was found to be 23 % of the wet weight.

concentrated suspensions respire about as much as slices, sometimes even more. Dilution destroys the respiration more or less in proportion to the extent of the dilution.

Macfadyen *et al.* (for references see Harden [1932]) and Warburg [1911; 1914] have described similar observations. Macfadyen *et al.* found that the alcoholic fermentation of yeast juice disappears with dilution. Warburg investigated the effect of dilution on the respiration of laked blood corpuscles of the goose. He cytolysed the cells by freezing and thawing. The oxygen uptake of the concentrated cytolysed red cells was 60–75 % higher than that of the intact cells. When the cells were diluted in the proportions 2:5:11, the oxygen consumption was in the proportions 66:31:15. Thus the increase of respiration after destruction of the cells and the decrease on dilution are very similar in red cells and in kidney.

It should be mentioned that the experiments described in this section were carried out with freshly prepared "brei". "Brei" which had been kept on ice for 24 hours gave only a small oxygen uptake as compared with fresh "brei".

These results lead to a distinction between enzymes or systems which act independently of the amount of fluid in which they are dissolved or suspended and systems which act only within a small range of concentration and are destroyed if the medium is diluted. The vast majority of the common enzymes belong to the first group. The second group comprises those reactions which have generally been considered as being bound up with the structure of the living cell, *i.e.* the bulk of oxidations and fermentations.

(3) *Theory of the effect of dilution.* The effect of dilution can be explained by the assumption that a reaction between more than two partners (a ternary collision or a collision of a higher order) determines the velocity of the reaction. Such components may be for instance activated substrate, activated oxygen and a co-enzyme. The probability of a ternary collision decreases in proportion to the dilution. If one volume of enzyme solution is diluted with one volume, the number of ternary collisions is halved in the total volume of the mixture. In many experiments in Table XXVIII, the effect of dilution is that expected for a ternary collision.

Ternary collisions occur extremely rarely in homogeneous solutions. It is one of the functions of the structure of the cell to arrange the catalysts in such a way that a ternary collision reaches a certain degree of probability. Of course this is not the only reason why the structure is of importance for chemical reactions in cells. It is not however within the scope of this paper to discuss this problem in full.

Thus the different behaviours of the *d*- and *l*-amino-acid deaminases on extraction and dilution appear to be due to the different structures of the two enzymic systems. The *d*-enzyme is a comparatively simple system, the *l*-enzyme a more complicated one in which an additional factor, involving a ternary collision, plays a part.

#### VII. INTERRELATION BETWEEN *d*- AND *l*-AMINO-ACID DEAMINASES.

From the experiments described, it was concluded that two different deaminating systems exist. But it must be pointed out that this difference only concerns the two systems as whole systems. It may well be that the two systems have certain components in common; for instance it may be that the *l*-deaminase is the *d*-deaminase *plus* an additional factor. The idea that the *d*-deaminase is a fragment of the *l*-amino-acid deaminase is supported by the fact that *d*-deaminase can be obtained only from those tissues which contain the *l*-system, and by the fact that the *l*-system cannot be separated from the *d*-system. Moreover it would explain the occurrence of an enzyme for which practically no substrate is found in nature. If this view is correct, the additional factor, which makes the *d*-enzyme into the *l*-enzyme, is a substance which reacts with *l*-amino-acids and enables them to react in the same way as *d*-amino-acids react by themselves without an auxiliary substance.

#### SUMMARY.

1. Slices of liver and kidney deaminate (by oxidation) the optically "natural" amino-acids and also their optical isomerides which do not occur naturally.
2. The "natural" amino-acids, which according to their spatial configuration belong to the *l*-series, are not deaminated in the presence of octyl alcohol or *M*/100 cyanide, or in extracts of ground tissue or dried tissues.
3. The "non-natural" amino-acids which belong to the *d*-series are deaminated in the presence of octyl alcohol, of *M*/100 cyanide and in extracts of ground or dried tissues.
4. These differences between the deaminations of optical isomerides are explained by the assumption that deamination of the two stereoisomerides is brought about by two different enzymic systems ("*d*-amino-acid deaminase" and "*l*-amino-acid deaminase"). The difference concerns the two systems as whole systems; it may be that they have certain components in common or even that the *d*-amino-acid deaminase is a fragment of the *l*-amino-acid deaminase.

5. The activity of the deaminating systems under various conditions and their occurrence in various tissues and animals have been investigated.

6. The *l*-amino-acid deaminase is active in ground tissue when the "brei" is suspended in a small volume of fluid. On dilution of the tissue suspension, the activity disappears approximately in proportion to the dilution.

7. The cell respiration in ground tissue shows a similar sensitivity towards dilution.

8. The effect of dilution is explained by the assumption that a ternary collision, or a collision of a higher order, plays a rôle in those enzymic systems which become inactive on dilution. The probability of a ternary collision decreases in proportion to the dilution.

9. The deamination of *l*- and *d*-amino-acids in kidney slices is inhibited by substances which can be oxidised by kidney. If two different substances, each of which causes an increase in oxygen consumption, are added together to kidney or yeast, no summation of the effects on the oxygen uptake ensues. The substrates compete for the oxygen and displace each other. This indicates that the process of activation of oxygen is identical for all the substrates which show no summation.

This work was made possible by grants from the Rockefeller Foundation and the Ella Sachs Plotz Foundation.

I wish to express my deep gratitude to Sir F. G. Hopkins for welcoming me to his Laboratory and for his interest and help during the progress of the work. I wish also to thank Prof. D. Keilin for advice and criticism, Prof. C. R. Harington for a gift of  $\beta$ -hydroxyglutamic acid and Dr N. W. Pirie for a number of amino-acids.

# CXCVIII. A DISCREPANCY BETWEEN BIOLOGICAL ASSAYS AND OTHER METHODS OF DETERMINING VITAMIN A. <sup>1</sup>.

By RONALD SYDNEY MORGAN

(*Research Department, Lever Brothers, Limited, Port Sunlight*),

JOSEPH RATCLIFFE EDISBURY AND RICHARD ALAN MORTON

(*University of Liverpool*).

(*Received May 31st, 1935.*)

THREE methods are at present widely used for the determination of vitamin A, viz. (i) the fundamental method of biological assay, (ii) the measurement of the ultraviolet absorption at  $328m\mu$ , and (iii) the evaluation of blue-colour intensity in the antimony trichloride test. The colour test and the ultraviolet absorption owe their origin to the alcohol  $C_{20}H_{40}OH$  or its esters [Karrer *et al.*, 1931; 1933; Karrer and Morf, 1933; Heilbron *et al.*, 1932], and the biological activity shows a very high correlation with these tests. Refinement of all three methods has, however, revealed discrepancies, and the object of this paper is to show that some materials possess biological activity, indistinguishable from that of vitamin A, over and above that corresponding with the proportion of  $C_{20}H_{40}OH$  (or its esters) present in these preparations.

The reliability of the physicochemical tests as measures of vitamin A potency has already been the subject of much investigation. The antimony trichloride colour test was introduced in 1926 [Carr and Price, 1926], but on account of the errors then obtaining in biological assays, its validity could not be readily assessed [*cf.* Medical Research Council Committee Report, 1928]. The spectroscopic test was introduced in 1928 [Morton and Heilbron, 1928], and the first attempt to correlate biological and spectroscopic data on a quantitative basis was made shortly afterwards [Drummond and Morton, 1929]. The extremes in the intensity of absorption at  $328m\mu$  for the six cod-liver oils tested covered a range of only 3.25 to 1, and the biological assay could not be relied upon to differentiate clearly between oils differing in potency in a ratio of less than 2 to 1. Within the limitations of the comparison, however, the agreement was satisfactory.

A more comprehensive investigation was made by Coward *et al.* [1931]. Eleven cod-liver oils and two concentrates were studied, the range of potency being of the order 30 to 1. In this work Blue values in the colour test were determined in two ways: (i) in the ordinary way on the oils themselves, and (ii) on the unsaponifiable extracts from known weights of the oils. Ultraviolet data were recorded directly on the oils. Statistical methods showed that although there was a high degree of correlation between the physical and biological assays, the estimated errors of the biological test were not sufficient to account for the observed discrepancies. It was pointed out, however, that the biological test as carried out might have been liable to further error due to a variation in the average response of the animals to vitamin A at different

<sup>1</sup> The substance of this paper was read at the 166th meeting of the Biochemical Society (Liverpool, December 15th, 1934).

periods, and it has since been shown that the error from this source may be very large indeed [Coward *et al.*, 1933].

In further work on the same subject [Coward *et al.*, 1932] four oils from the same series were re-examined, and five new samples were studied. The results generally supported the conclusions of the first paper.

In the present work any error of the biological assay due to variation in the average response of rats to vitamin A at different periods has been eliminated by the use of the international carotene standard. Each assay has been made by direct comparison of the test substance with the standard preparation; for every rat that has received a dose of the test substance, another of the same litter and the same sex has received a comparable dose of the standard over the same period. It appears, therefore, that we are justified in assuming that the error of the biological assay, calculated from the variation in the difference of the growth of animals receiving doses in a known ratio, represents the total error of the assay.

It was pointed out in the previous papers of Coward *et al.*, noted above, that the ultraviolet assay carried out directly on liver oils is apt to give results erring on the high side owing to the presence of substances, other than vitamin A, which contribute to a variable extent to the observed absorption. This extraneous contribution is usually of the order 0.05–0.2 ( $E_{1\text{ cm}}^{1\%}$ ), which, although insignificant in comparison with the gross absorption of a rich oil (*e.g.* halibut,  $E_{1\text{ cm}}^{1\%} 328m\mu = 30$  or more), may introduce a serious error into determinations on weaker oils (*e.g.* cod,  $E_{1\text{ cm}}^{1\%} 328m\mu = 0.5\text{--}1.5$ ). When the antimony trichloride test is applied directly to a weak oil, there is an error in the opposite sense, which may be considerable, arising from the presence of substances which interfere with the development of the blue colour [cf. Morton, 1932]. If, however, the physico-chemical tests are, in such a case, applied not to the oil but to the total unsaponifiable matter from a known weight of oil, both these sources of error can be largely eliminated. In the present work, tests on the unsaponifiable fractions have accordingly been adopted in all determinations on cod-liver oils and materials of similar potency.

#### EXPERIMENTAL METHODS.

*Blue values* (Carr-Price-Lovibond)<sup>1</sup> were determined according to the method described in the British Pharmacopoeia (1932), the ether-extracted unsaponifiable fraction of the oil being employed where necessary. All Blue values were determined on more than one occasion.

*Spectroscopic measurements* were made of the intensities of absorption at the two characteristic maxima exhibited by the blue solution obtained in the antimony trichloride test (at 580–583, and 620  $m\mu$  for rich oils and unsaponifiable extracts; at 572 and 606  $m\mu$  for weaker oils), and of the intensity of absorption in the ultraviolet at or near 328  $m\mu$ . For the measurements made on the blue solution, a visual spectrophotometer was employed, and each recorded measurement was the mean of 10–12 readings rapidly taken on freshly prepared solutions, before appreciable fading could occur. For the measurement of the absorption at 328  $m\mu$ , a quartz spectrograph with long-focus sector photometer was employed.

For the preparation of unsaponifiable fractions required for spectroscopic examination, the following method, based on the recommendations of the Society

<sup>1</sup> For these determinations we are indebted to Mr H. Pritchard of the Research Department, Lever Brothers, Limited.

of Public Analysts for the determination of unsaponifiable matter [1933], was developed:

Saponify 0.2–1.0 g. of oil, according to potency, with 10 ml.  $N/2$  alcoholic KOH for 5–10 minutes. Dilute with 20 ml. water, and extract twice with 25 ml. freshly distilled ether. Wash the combined ethereal extracts once with water (swirling), once with dilute alkali, and then twice more with water (gently shaking), using 10–20 ml. for each wash. For the colour test evaporate an aliquot portion of the ethereal solution and blow dry twice with nitrogen or carbon dioxide at 70–80°, after adding a few drops of pure ethyl alcohol. Make up the residue to suitable volume with pure dry chloroform and examine without delay. For the examination of ultraviolet absorption, evaporate a second aliquot portion of the ethereal extract in a stream of nitrogen or carbon dioxide and dissolve the wet residue in alcohol that has been tested spectrographically for transparency. The use of porous pot (to prevent “bumping”) should be avoided, since adsorption of appreciable quantities of vitamin A on the pot may occur.

*Biological assays* were carried out according to the method recently described [Morgan, R. S., 1934], using a diet with meat meal and coconut meal as sources of protein. The paper referred to contains an example showing how assays are calculated from growth data (Cod-liver oil II in the present series of tests). In this example the oil was considerably more potent than was expected, and the growth response exceeded that produced by the comparative dose of standard in 17 of the 18 pairs of animals. In many tests, however, the assays were very near the expected potencies, *i.e.* the growth responses produced by the standard and the test substance were nearly equal. In some tests, the experimental period was 6 weeks, growth being averaged at 4, 5 and 6 weeks, and in others the experimental period was 3 weeks. In these, the initial and final weights of the rats were taken as the average of the weights on three consecutive days.

In all assays the reference substance was the 1931 carotene standard of which  $1\gamma = 1$  unit. The colour of every new solution of the standard was matched in the Lovibond tintometer, the solution being diluted with chloroform until a match of about 5 yellow was obtained in a 1 cm. cell. The matches on successive solutions were constant within the error of the determination and gave an average value, calculated to a 1 % solution of the carotene, of 12,250 yellow + 3050 red.

## RESULTS.

### *Spectroscopic examinations.*

The details of the results of the spectroscopic examinations are given in Table I. In calculating the percentage of vitamin A, the rich concentrate described by Carr and Jewell [1933] has been accepted provisionally as the pure substance. This material has a Blue value of 80,000 and the following spectroscopic characteristics:  $E_{1\text{ cm.}}^{1\%}$  620  $m\mu$  5000, 583  $m\mu$  2600, 328  $m\mu$  1600. Percentages have been calculated by simple proportion. Those based on the extinction coefficients of the blue solution with antimony trichloride tend to represent lower limits, because of inhibition, whilst those based on the extinction at 328  $m\mu$  represent upper limits. It will be noticed that the two sets of values approach each other closely in many unsaponifiable extracts and other rich materials, in which the effects of inhibition and extraneous absorption are slight. The extinction at 583  $m\mu$  is, however, not always easy to determine accurately, and slight discrepancies here may be ignored.

### *Biological assays and Blue values.*

The results of the biological assays and Blue value determinations are also summarised in Table I. The ratios assay/Blue value and assay/spectroscopic data have been brought to the same basis by expressing each as the assay extrapolated

to "pure vitamin A". In all assays thus extrapolated from data on low-potency oils, the figures obtained *via* the unsaponifiable fractions have been used.

Details of the biological assays of three of the substances are given below.

*Assay No. 12. Vitamin A distillate.* Doses were chosen on the expectation of a potency of about 1.2 million units per g., *i.e.* a dose of 1/1200 mg. was fed in comparison with 1 unit of the standard. The growth responses in 3 weeks were as follows (all the animals were bucks).

	Standard g.	Concen- trate g.		Standard g.	Concen- trate g.
$\frac{1}{2}$ -unit pairs	40.7 16.0	35.6 11.0	1-unit pairs ( <i>cont.</i> )	40.7 15.4	49.0 32.0
$\frac{3}{4}$ -unit pairs	31.3 0	51.4 26.3		21.6 44.7	34.0 42.0
	22.7	30.0	2-unit pairs	53.0 83.7	57.7 63.0
1-unit pairs	55.6 57.0 56.0 52.7 52.6	57.7 70.7 57.0 51.0 56.0		66.7	60.7
			Positive controls	71.3 79.0 88.3	— — —

The growth response produced by the concentrate was superior to that produced by the comparative dose of standard in 11 of the 17 pairs. The average value of the pair difference of the squares of growth is  $-186$ , corresponding to a dose ratio of 1.075.

Assay = 1.29 million units per g.

*Assay No. 15. Liver oil from the fish Thyrsites atun.* Doses were chosen on the expectation of a potency of about 16,750 units per g. The growth responses in 3 weeks were as follows (all bucks).

	Standard g.	Liver oil g.		Standard g.	Liver oil g.
$\frac{1}{2}$ -unit pair	26.3	16.7	2-unit pairs ( <i>cont.</i> )	44.1 58.0	52.7 61.4
1-unit pairs	42.3 57.3 38.7 30.0	47.7 53.3 39.4 38.3		41.0 53.0	45.7 42.4
2-unit pairs	58.3	60.7	Positive control	78.7	—

The growth response produced by the liver oil was superior to that produced by the standard in 7 out of the 10 pairs. The average value of the pair difference of the squares of growth is  $-212$ , corresponding to a dose ratio of 1.085.

Assay = 18,200 units per g.

*Assay No. 23. Commercial cod-liver oil concentrate II.* Doses were chosen on the expectation of a potency of about 40,000 units per g. Growth responses in 3 weeks were as follows (all bucks).

	Standard g.	Concen- trate g.		Standard g.	Concen- trate g.
$\frac{1}{2}$ -unit pairs	27.3 23.7	28.6 12.3	1-unit pairs ( <i>cont.</i> )	63.7	43.7
$\frac{3}{4}$ -unit pair	38.3	37.6	2-unit pairs	62.3 68.3 60.6 55.7	37.5 57.6 60.7 62.6
1-unit pairs	45.0 30.0 47.4 30.3 46.3	40.3 25.0 31.4 29.3 31.0	Positive controls	71.3 76.6 83.7	— — —

													0.62

Three of the substances were also assayed in other laboratories as part of the preparatory work for the 1934 meeting of the League of Nations Health Organisation Permanent Committee on Biological Standardisation. The average assay of Cod-liver oil "Z" (Assay No. 2) was 1500 units per g., a value about 50 % higher than the individual value in Table I, but the average assays of Cod-liver oil "X" (Assay No. 8) and the vitamin A distillate (Assay No. 12) were in close agreement with the individual values reported here.

Cod-liver oil IV was a bulk sample prepared from 64 samples of medicinal cod-liver oil, and Cod-liver oils I and II were bulk samples prepared from the oils below and above median blue value respectively, in the same series. The assays of these oils have been reported in full elsewhere [Morgan and Pritchard, 1935].

The sample referred to as Fish-liver oil "A" (Assay No. 3) was described as cod-liver oil, but the percentage of unsaponifiable matter was above the B.P. limit, and this, together with the high Blue value, suggests that the sample was not genuine cod-liver oil.

The growth response produced by the concentrate was inferior to that produced by the standard in 11 of the 13 pairs. The average pair difference of the squares of growth is 670, corresponding to a dose ratio of 1/1.297.

$$\text{Assay} = 30,900 \text{ units per g.}$$

#### STATISTICAL EXAMINATION OF THE RESULTS.

##### *Correlation between Blue value and biological assay.*

(In the calculations made in this section, the assays Nos. 16 and 17, for which there are no spectroscopic data, have been omitted, so that the results may be comparable with those of similar calculations made for the correlation between spectroscopic estimates and biological assays.)

In Table II, the assays extrapolated to "100 %" vitamin A from the Blue values have been arranged in order. The number of pairs of rats used in each assay is given as the equivalent number of pairs of male rats in a 3-week test, on the basis that an assay with 10 pairs of males will be of the same accuracy as one with 20 pairs of females, and that a 4, 5, 6-week assay with 10 pairs will be of the same accuracy as a 3-week assay with 12.2 pairs. The limits of error corresponding to twice the standard error (=three times the probable error) of the biological assays, have been calculated from the number of pairs of animals used in each test and the standard deviation of the difference in the squares of growth of male rats receiving doses in the ratio 2/1.

Table II. Assays extrapolated to "100 %" vitamin A (Blue value = 80,000) from the Blue values.

Assay No.	No. of pairs as males in 3-week tests	Substance assayed	Assay of "100 %" vitamin A, millions of units per g.	Limits of error corresponding to twice the standard error
1	10.4	Commercial C.L.O. conc. I	1.23	0.99-1.66
21	8	Mammalian L.O. + C.L.O. conc. (ii)	1.26	0.90-1.77
23	13	Commercial C.L.O. conc. II	1.29	0.99-1.69
5	7.9	Mammalian L.O. unsap.	1.35	0.96-1.90
11	17.6	Mammalian L.O. dilute solution	1.38	1.10-1.74
20	7	Mammalian L.O. + C.L.O. conc. (i)	1.43	0.99-2.06
19	7	Mammalian L.O. III	1.44	1.00-2.07
12	17	Vitamin A distillate	1.53	1.21-1.94
22	6	Tunny-liver oil	1.56	1.05-2.31
4	12.8	Mammalian L.O. I	1.58	1.21-2.07
18	8	Mammalian L.O. II	1.63	1.16-2.29
24	11	Crude C.L.O. "B"	1.68	1.26-2.24
13	7	Halibut-liver oil	1.71	1.19-2.46
3	9.2	Fish-liver oil "A"	1.95	1.43-2.66
10	8.5	Unsap. from C.L.O. IV, prep. 1	2.06	1.48-2.87
14	13	Unsap. from C.L.O. IV, prep. 2	2.09	1.60-2.73
15	10	L.O. from <i>Thyrsites atun</i>	2.2	1.62-2.98
6	17	C.L.O. I	2.22	1.76-2.80
9	13.7	C.L.O. IV	2.31	1.78-2.99
2	17	C.L.O. "Z"	2.36	1.87-2.98
7	17	C.L.O. II	2.65	2.10-3.35
8	8.5	C.L.O. "X"	3.38	2.43-4.70

Since the errors of the biological assay are calculated logarithmically (*i.e.* the range of error of an assay is expressed by the mean multiplied or divided by a factor, not *plus* or *minus* a difference), the average of the assays extrapolated to pure vitamin A is best calculated *via* the logarithms. The value so obtained is 1.766 million units per g. Seven assays of the twenty-two differ

from this mean by an amount which is equal to or greater than twice the standard error of the assay. It is evident, however, that if two assays differ significantly from the mean in opposite directions, they differ very significantly from each other. The distribution of the assays extrapolated to "pure vitamin A", and their errors, are shown diagrammatically in Fig. 1, but the error

Fig. 1. Biological assays extrapolated to "pure vitamin A" from the Blue values (Assay  $\times$  80,000/n.v.).

Each assay is represented by a point, and the limits of error corresponding to 1.41 times the standard error are shown by the unshaded area on either side of each point. The numbers on the left are the assay numbers given in Table I; they give the order in which the assays were carried out. The letters on the right indicate the class of substance assayed, thus: *M* = mammalian liver oils and concentrates; *CN* = commercial cod-liver oil concentrates; *C'* = medicinal cod-liver oils and concentrates prepared from them. *F* = fish-liver oils other than medicinal cod-liver oils; *D* = vitamin A distillate.

The two assays marked \* (for which no spectroscopic data are available) have been omitted in calculating the average, so that the averages of the assays of "pure vitamin A" calculated from Blue values and from extinction coefficients, may be comparable.

range in the diagram (shown by the unshaded area on either side of each point) is given by  $\sqrt{2}$  times the standard error. If the errors of two assays, calculated in this way, are approximately equal (in a ratio of not more than 2/1), and just fail to overlap, then the difference between the two assays is approximately equal to twice the standard error of the difference and may be considered significant. Examination of Fig. 1 shows that there are 17 assays significantly lower than the highest, 11 assays significantly higher than the lowest *etc.*

The average of the logarithms of the assays calculated to "pure vitamin A" in millions of units per g. is  $\log 1.766 = 0.247$ . The standard deviation of this value is 0.117. Taking the limits of error as twice this error (*i.e.* to give approximately the 22/1 chance) the limits of error of the Blue value as an estimate of the biological assay are 58.3–171.4 % of the found value.

#### *Correlation between spectroscopic estimations of vitamin A and biological assays.*

The assays extrapolated to "pure vitamin A" from the spectroscopic estimations have been arranged in order in Table III. The limits of error corresponding to twice the standard error of the biological assays have been calculated as in Table II. The numbers of pairs of rats used for the assays have already been given in Table II.

Table III. Assays extrapolated to "100 %" vitamin A from the spectroscopic estimations.

Assay No.	Substance assayed	Assay of "100 %" vitamin A, millions of units per g.	Limits of error corresponding to twice the standard error
4	Mammalian L.O. I	1.08	0.83-1.41

The distribution of the assays calculated to "pure vitamin A" and their errors calculated as  $\sqrt{2}$  times the standard error, are shown diagrammatically in Fig. 2.

Fig. 2. Biological assays extrapolated to "pure vitamin A" from the spectroscopic estimates of the percentage present. The significance of the letters and the numbers is the same as in Fig. 1.

The logarithmic mean of the assays calculated to "pure vitamin A" is 1.73 million units per g. The standard deviation of the logarithm of this value is 0.1098, and thus the limits of error of the spectroscopic value as an estimate of the biological assay are calculated as 60.3-165.8 % of the found value.

#### *Correlation of Blue value and extinction coefficient at 328m $\mu$ .*

The values of the ratio Blue value/extinction coefficient are arranged in ascending order in Table IV.

Table IV. *Values of the ratio Blue value/extinction coefficient at 328m $\mu$ .*

	B.V./E.		B.V./E.
Mammalian L.O. I	34.4	Mammalian L.O. III	49.3

C.L.O. I	42.3	Tunny-liver oil	52.5
C.L.O. "X"	42.3	Crude C.L.O. "B"	53.2
C.L.O. II	44.0	Mammalian + C.L.O. conc. (ii)	53.5
Mammalian L.O. unsap.	44.0	Mammalian + C.L.O. conc. (i)	53.7
Commercial C.L.O. conc. I	44.1	Mammalian L.O. II	56.9
Mammalian L.O. dilute solution	44.4	Commercial C.L.O. conc. II	59.9
C.L.O. IV	45.5	Liver oil from <i>Thyrstles atun</i>	60.9
C.L.O. "Z"	47.5	Vitamin A distillate	61.3

The logarithmic mean of these values is 48.5, and the standard deviation of the logarithm is 0.0683. The limits of error of the Blue value as a means of predicting the extinction coefficient that will be found are 73–137 % of the found value (twice the standard error of a single determination with one sample).

If it is assumed that Blue value and extinction coefficient at 328m $\mu$  are really measures of the same thing, the error calculated above represents the sum of the independent errors of the Blue value and the extinction coefficient determinations. It will be somewhat greater than the sum of the errors of the Blue value determination and the spectroscopic estimates, since the latter take into account the absorption of the blue solution as well as the absorption at 328m $\mu$ .

The possible sources of error are:

(i) Instrumental, viz. from  $\pm 3$  % in routine spectrophotometry to  $\pm 10$  % in Lovibond readings.

(ii) Failure to effect 100 % recovery of vitamin A in the unsaponifiable fraction. This source of error is not significantly operative in careful work.

(iii) The presence of substances other than vitamin A absorbing in the near ultraviolet and remaining in the unsaponifiable fraction. This source of error is normally of no consequence, but in certain preparations of crude oils and mammalian extracts, a real difficulty arises.

(iv) The depth of blue colour in the antimony trichloride test may be subject to variations depending on the exact composition of the reagent, and the personal factor in matching a somewhat variable blue tint against standard Lovibond glasses may be a further source of error.

(v) In the colour test, inhibitors may not be completely eliminated from the unsaponifiable extract.

(iii) and (v) operate in opposite senses, but the main conclusions of this paper are the same, whether the biological assays are compared with colour tests or with ultraviolet absorption.

The most significant source of error, when it occurs, is (iii) (*vide infra*).

*Allowance for the errors of the biological assay, the Blue value and the spectroscopic estimate in the above correlations.*

The following values of the standard errors of the logarithms of ratios and the limits of error of one variable estimated from another have already been calculated:

Table V.

Ratio X/Y	Standard deviation of the logarithm $\lambda$	Limits of error of X predicted from Y (2 $\lambda$ range %)
(1) Assay/Blue value	0.117	58.3–171.4
(2) Assay/spectroscopic estimate	0.1098	60.3–165.8
(3) Blue value/extinction coefficient	0.0683	73.0–137.0

The error of the biological assay has been dealt with in the paper describing the technique [Morgan, R. S., 1934]. The limits of error given there have been substantially confirmed by subsequent data, and the value of the standard error of the logarithm of an assay with 11.2 pairs of male rats in a 3-week test (the average number used in this series) is calculated as 0.064. This figure is calculated from the variation in the difference of the squares of growth of animals receiving doses of vitamin A in the ratio 2/1 and gives an overestimate of the average error, since the ratio of the doses of vitamin A supplied by the standard and the test substance was generally much nearer 1/1. (This point is discussed in the paper referred to above.) The amount of variation in the ratio assay/Blue value that is due to the error of the biological assay may now be allowed for, by subtracting the logarithmic variances, thus:

$$\lambda^2 \text{ of assay/Blue value} - \lambda^2 \text{ of assay} = \lambda^2 \text{ of vitamin A potency/Blue value}$$

$$0.01372 - 0.0041 = 0.00962.$$

$$\lambda \text{ of vitamin A potency/Blue value} = \sqrt{0.00962} = 0.0981.$$

The limits of error corresponding to twice this value are 63.6–157.1 %. This gives the error of the found Blue value as an estimate of true vitamin A potency. In the same way the logarithmic variance of the ratio vitamin A potency/spectroscopic estimate is calculated as 0.00794, giving the standard error of the logarithm as 0.0891, and limits of error of 66.5–150.8 %.

Since the logarithmic variance of the found Blue value, as a measure of vitamin A potency, exceeds that of the spectroscopic estimate, as the same measure, by  $0.00962 - 0.00794 = 0.00168$ , it may be assumed that the logarithmic variance of the Blue value determinations exceeds that of the extinction coefficient determination by the same amount. Thus the variance of the ratio true/found extinction coefficient may be calculated as

$$(0.0683^2 - 0.00168)/2 = 0.0015,$$

and the variance of the ratio true/found Blue value as

$$0.0015 + 0.00168 = 0.00318.$$

If all the above values are adjusted for the number of observations, the values given in Table VI are obtained.

Table VI. *Variation in ratios of biological, chemical and physical assays of vitamin A.*

Ratio $X/Y$	$4\lambda^2$ adjusted for No. of observations	$X$ predicted from $Y$ . Range within which 21 out of 22 obser- vations will lie %
Assay/Blue value	0.06126	56.6–176.8
Assay/spectroscopic estimate	0.05382	58.6–170.6
Blue value/extinction coefficient	0.02126	71.5–139.9
Assay (i.e. vitamin A potency/Growth of animals)	0.01636	74.5–134.3
Vitamin A potency/found Blue value	0.04490	61.3–162.9
Vitamin A potency/spectroscopic estimate	0.03746	64.0–156.2
True/found Blue value	0.01435	76.0–131.7
True/found extinction coefficient	0.00691	82.5–121.2
Vitamin A potency/true Blue value	0.03055	66.9–149.6
Vitamin A potency/true extinction coefficient		

(In calculation of the above figures, the error of the spectroscopic estimate has been taken as equal to that of the determination of the extinction coefficient at  $328m\mu$ .)

Thus, even after allowing for the computed errors of the biological and the chemical or physical assays, the value of the ratio vitamin A potency/Blue value or extinction coefficient covers a range of about 2 to 1; the observed variation cannot be accounted for by the known errors of the biological, chemical or physical assays.

#### DISCUSSION.

The values of the individual assays extrapolated to "pure vitamin A" from either the Blue values or the spectroscopic estimates cover a range of about 2.7 to 1. It has been shown that many of the assays differ significantly from one another, and that even after allowing for the computed errors of the tests, a range of about 2 to 1 remains to be accounted for. Further evidence that this discrepancy is a real one is obtained from consideration of two assays which were carried out at the same time and both repeated after an interval of 6 months. The U.S.P. reference oil dated June, 1933 (Oil "X"), was assayed in February, 1934, at 2840 units per g. The Blue value was 67, indicating the presence of 0.084 % "pure vitamin A", and the spectroscopic estimate was 0.098 %. A second biological assay was made in September, 1934, and a value of 2468 units per g. was obtained (87 % of the original value); the Blue value had fallen to 62.5 (93 % of the original value)<sup>1</sup>. Thus the second assay may be regarded as a confirmation of the first.

The dilute solution of mammalian liver oil (Assay No. 11) had a Blue value of 64, indicating the presence of 0.08 % of "pure vitamin A", and the spectroscopic estimate was 0.09 %. It would therefore be expected to have about the same potency as the cod-liver oil, Oil "X", but the assay (in February, 1934) was 1060 units per g., only 37 % of the potency of Oil "X". When the assay was repeated in September, 1934, the value obtained was 1140 units per g., a confirmation of the first value, and the Blue value had not fallen.

Examination of Tables II and III and Figs. 1 and 2 shows that the highest values of the assays calculated to "pure vitamin A" are generally those of cod-liver oils of medicinal grade, and that the lowest values are those of mammalian liver oils and commercial cod-liver oil concentrates. Potent fish-liver oils occupy an intermediate position. These observations might suggest the following possibilities:

(i) That the vitamin A of cod-liver oil undergoes a loss of activity on saponification not associated with any change in its ultraviolet absorption or chromogenic properties.

(ii) That the Blue values and extinction coefficients of the medicinal grade cod-liver oils have been grossly underestimated because of failure to effect complete recovery of vitamin A in the unsaponifiable fractions prepared for the determinations.

(iii) That the extinction coefficients of the mammalian liver oils and commercial cod-liver oil concentrates have been grossly overestimated because of the poor persistence<sup>2</sup> of the 328m $\mu$  absorption band.

<sup>1</sup>  $E_{1\text{ cm}}^{1\%}$  328m $\mu$  on another sample of the same oil has recently (April, 1935) been found to be 1.33 (i.e. 84 % of original value).

<sup>2</sup> Persistence is taken as the difference between the absorption intensities at 328m $\mu$  (the maximum or head of the vitamin A absorption band) and at ca. 260m $\mu$  (the minimum in the same curve). In a normal unsaponifiable fraction the persistence is approximately 60-70 % of the value at 328m $\mu$ .

It does not appear likely, however, that the observed variation in the assays calculated to "pure vitamin A" can be accounted for by these causes. The following comments on each possibility may be made:

(i) The cod-liver oil "B", used in the preparation of commercial cod-liver concentrate II, gave an assay calculated to "pure vitamin A" close to the mean of the whole series and lower than that of any of the medicinal grade cod-liver oils. Preparations of unsaponifiable matter from two of the oils of medicinal grade gave assays, calculated to "pure vitamin A", higher than those of any oils except the medicinal oils and the liver oil of the fish *Thyrssites atun*.

(ii) To reduce the average assay, calculated to "pure vitamin A", of the five cod-liver oils at the end of Table IV to the average of the whole series, it would be necessary to assume a 24 % loss of vitamin A in the extraction of the unsaponifiable matter for the extinction coefficient determination. For these oils, however, the average ratio of the extinction coefficient determined directly to that determined *via* the unsaponifiable matter, was 1/0.87, *i.e.* the combined effects of (a) any loss of vitamin in the extraction process, and (b) the elimination of substances, other than the vitamin, capable of contributing to the gross absorption at  $328m\mu$  account for a difference of only 13 %. Tests with richer oils show that (b) is reduced to negligible dimensions by the technique here used. The feeding experiments referred to above, with unsaponifiable fractions of two of the oils, furnish further evidence that the Blue values and extinction coefficients of cod-liver oils determined *via* the unsaponifiable matter are not likely to suffer from any considerable error that does not affect direct determinations made on potent oils and concentrates. Two experiments were made with Cod-liver oil IV, and one with Oil "X". For these experiments, about 10 g. of the cod-liver oil were saponified and the unsaponifiable matter was extracted with peroxide-free ether (distilled after standing over sodium wire); an aliquot part of the ether extract was taken for the determination of Blue value, and the remainder was mixed with arachis oil containing quinol and freed from ether by evaporation in a stream of carbon dioxide or nitrogen. The determination of the Blue value of an aliquot part of the unsaponifiable matter, without addition of arachis oil, showed that the recovery was about equal to that obtained in the routine determination of Blue value *via* unsaponifiable matter. The arachis oil solution of unsaponifiable matter was then fed in comparison with the original oil and the percentage recovery of vitamin A determined from the comparative growth responses. In the first and third experiments the animals were divided into litter-mate triads, one of each triad receiving the standard, another receiving the oil and the third receiving the unsaponifiable matter; in the second experiment, the standard was omitted. The respective assays showed recoveries of 89.4, 90.5 and 87 % (all within the limit of 13 % loss indicated by the comparison of extinction coefficients determined directly and *via* the unsaponifiable matter), but the recoveries were probably rather better than these, for in the first two experiments there was some loss of Blue value on storage of the arachis oil solution of the unsaponifiable matter.

(iii) In some of the commercial cod-liver oil concentrates and mammalian-liver oils, the  $328m\mu$  band showed poor persistence or was entirely masked by other more intense absorption further in the ultraviolet. This absorption was not eliminated by saponification and cannot at present be accounted for. Generally, the ultraviolet results were in satisfactory agreement with the extinction at  $620m\mu$ ; in cases of appreciable discrepancy the latter values were taken in extrapolating to "pure vitamin A". It must not be overlooked, however, that the substance(s) responsible for the extraneous absorption in the

ultraviolet, although possibly biologically inactive or less active than vitamin A, may yet conceivably be chromogenic towards antimony trichloride in a similar manner to vitamin A and so account for the unusually low values extrapolated from both the ultraviolet and colour test figures. There is some evidence that the  $583m\mu$  band is stronger than usual whenever the ultraviolet absorption is anomalous.

It will be observed that the biological assays are expressed in terms of International Units, the 1931 standard carotene having been used as reference substance. This material, according to physical tests, contained about 68 % of carotene, the remainder being probably impurities or decomposition products. The 1931 standard might thus be expected to show about two-thirds of the activity of pure  $\beta$ -carotene. This is in good agreement with the observation reported to the 1934 League of Nations Commission that  $0.6\gamma$   $\beta$ -carotene was biologically equivalent to  $1\gamma$  of the 1931 standard preparation. The redefinition of the International Unit in terms of  $0.6\gamma$  pure  $\beta$ -carotene, thus involves  $1.66 \times 10^6$  i.u. per g. for  $\beta$ -carotene.

A simple calculation is here instructive. If the reaction:

proceeds quantitatively *in vivo* in the avitaminotic rat, 536 parts by weight of  $\beta$ -carotene yield 572 parts of vitamin A, and if this vitamin A is responsible for the growth effect, we have:

$$1 \text{ g. } \beta\text{-carotene} \rightarrow 1.067 \text{ g. vitamin A} \equiv 1.66 \times 10^6 \text{ i.u. per g.}$$

Hence 1 g. of vitamin A corresponds, on this basis, to  $1.56 \times 10^6$  i.u.

Now let us consider the vitamin A distillate (No. 12 in Table I) containing 70 % of vitamin A by the physicochemical assays. The potency in i.u. observed in different laboratories leads to a value very near to  $1.3 \times 10^6$  i.u. per g., corresponding to  $1.86 \times 10^6$  i.u. per g. for the pure vitamin. This result suggests that the conversion of carotene into vitamin A is substantially quantitative *in vivo*, at the experimental dosage used.

The whole validity of the carotene standard rests upon the assumption of a constant efficiency in this conversion, and if the basis of the redefinition of the international standard is borne in mind, there is little room for doubt that the reaction can be quantitative at the levels of dosage used in vitamin assays. This is supported by the fact that  $\beta$ -carotene, which from its structure can yield two molecules of vitamin A, is twice as active as  $\alpha$ -carotene, which can yield only one.

If now we turn to Oil "X", emphasis must be laid on the excellent agreement between the spectroscopic colour test and ultraviolet absorption, both carried out on the unsaponifiable extract. The percentage vitamin A is 0.098 to within  $\pm 2$  %. The biological assay rests on as rich a body of data as any vitamin A assay yet made, namely nine assays carried out in U.S.A. (mean 3000 i.u. per g.) and several concordant assays in this country. If we accept the figure given in this work, namely 2840 i.u. per g., the calculated figure for 100 % vitamin A must be  $2.9 \times 10^6$  i.u. per g. This is so much higher than the theoretical value of  $1.56 \times 10^6$  i.u. per g. as to be outside the known range of experimental error.

There seems, therefore, to be no escape from a real discrepancy, which does not appear to be due to biological differences between vitamin A as an alcohol and vitamin A as an ester. The simplest assumption is that cod-liver oil "X"

contains a biologically active substance distinct from the vitamin A which is usually associated with the formula  $C_{20}H_{20}OH$ .

It is not unlikely that in the decomposition of vitamin A, biological activity may disappear earlier than selective absorption and chromogenic power. Although the inactive substances formed might show selective absorption and chromogenic power differing qualitatively from those shown by the original active substance, they might interfere with the measurement of the absorption and chromogenic power of any active substance with which they were admixed and thus lead to an anomalous physical assay erring on the high side. A physical assay lower than would be expected from the biological assay, cannot be accounted for in this way.

*Note on a paper by Lathbury [1934].*

Since a recent paper by Lathbury reports work similar to that described in the present paper, but gives conclusions somewhat different from those arrived at here, it is necessary to consider it in some detail. Her technique differed from ours in the following particulars:

(i) A quantitative interpretation of the biological tests, based on the actual growths of the animals, was not attempted. The standard and the oil to be examined were each fed at two levels, and if the growths produced by the comparative doses were of the same order, the standard and test substance were considered to supply equal amounts of vitamin A at the levels fed. The ratio assay/Blue value was usually a round number (40/1, 25/1 or 20/1) following apparently from the use of the Blue value as guide to dosage level.

(ii) Blue values *via* the unsaponifiable matter were determined by the method of Smith and Hazley [1930] in which chloroform is used to extract the unsaponifiable matter.

(iii) Extinction coefficients of cod-liver oils were determined directly instead of *via* the unsaponifiable matter.

For purposes of comparison, the values given in Tables IV and V in Lathbury's paper have been converted into the form in which the data of this paper are presented, those assays which are given only as limits being omitted.

		Assay extrapolated to "pure vitamin A" (millions of units per g.)	
		From the Blue value	From $E_{328m\mu}$
Liver oil	A	3.20	(0.64)*
	Z	3.20	2.00
	G	3.20	1.84
	B	3.20	2.73
	X	3.55	2.26
	Y	3.58	1.75
Logarithmic average (omitting oil A)		3.34	2.09
Concentrate	E	1.60	1.68
	F	1.60	1.42
	J	1.60	—
	K	1.60	1.69
	Q	1.60	1.60
	D	2.00	2.33
	N	2.00	2.00
	R	2.00	2.09
Logarithmic average (omitting conc. J)		1.76	1.81

\* The extinction coefficient of oil A is given as 0.8. This value is abnormally high because of the interfering effect of absorbing substances which can be removed by saponification. The net value, *via* the unsaponifiable matter, determined by one of us (J. R. E.) was 0.36.

The extreme variation in the assays extrapolated to "pure vitamin A" from the Blue values, is from 1.6 to 3.58 million units per g. The values calculated from the data on cod-liver oils are generally higher than those obtained in the present work, but this can be attributed to the difference in the techniques of determining the Blue value *via* the unsaponifiable matter. The use of ether instead of chloroform for extracting the unsaponifiable matter usually results in higher Blue values being obtained, because destruction of vitamin A by chloroform during the concentration of the extract is avoided.

The extreme variation in the assays calculated to "pure vitamin A" from the spectroscopic data is from 1.42 to 2.73 million units per g., compared with 1.08–2.9 in the present work. The mammalian-liver oils and commercial cod-liver oil concentrates, however, are not represented in Lathbury's series, and if they are omitted from the present series, the extreme variation is 1.54–2.9. It is not possible to calculate whether the substantial variation in Lathbury's series is significant of a real discrepancy, since data for the sampling error of the biological assay are not available. The average value for the oils (2.09 million units per g.) is slightly higher than that calculated for the concentrates (1.81 million units per g.), and presumably if the extinction coefficients of the oils had been determined *via* the unsaponifiable fractions, the average value for the oils would have been raised to about 2.4 million units per g.

Thus Lathbury confirms a discrepancy between biological assays and Blue values, and her results cannot be held to exclude the existence of the discrepancy between biological and physical assays noted here.

There is a very close agreement between the average assays of concentrates calculated to "pure vitamin A" in Lathbury's series and the average assays calculated for all oils examined in the present work:

	Assays extrapolated to "pure vitamin A" (millions of units per g.)	
	From Blue values	From spectroscopic data
Lathbury's concentrates	1.76	1.81
All oils in the present work	1.77	1.73

#### SUMMARY.

Biological assays for vitamin A, Lovibond Blue values, and spectroscopic estimates of the percentage of vitamin A ( $C_{20}H_{29}OH$ ) present, are given for a series of 22 oils and concentrates covering a range of potency of 530 to 1,290,000 international units per g.

From the assay of each substance, and the physicochemical tests made, the potency of "100 %" vitamin A has been calculated, the characteristics of the rich concentrate described by Carr and Jewell [1933] being accepted as those of the pure substance.

The assays so expressed vary from 1.23 to 3.38 million units per g. when calculated from the Blue values (mean 1.77), and from 1.08 to 2.9 million units per g. when calculated from the spectroscopic estimates (mean 1.73). This variation is greater than can be accounted for by the known errors of the assays and the physicochemical measurements; allowance for these errors leaves a range of variation from 67 to 150 % of the mean value to be accounted for.

Generally the highest values are given by cod-liver oils of medicinal grade. The highest of all in the series examined was given by the U.S.P. reference oil; this has been assayed in several other laboratories and the results are in close

agreement with that given in the present work. Evidence is presented that the high values obtained are not due to gross underestimation of the Blue values or the spectroscopic absorptions.

From the recent redefinition of the unit of vitamin A as the activity of 0.6 $\gamma$  of  $\beta$ -carotene<sup>1</sup>, it is calculated that if  $\beta$ -carotene is converted efficiently into vitamin A at the levels of dosage used in assays, the potency of pure vitamin A would be 1.56 million units per g.; this is of the same order as the mean for the whole series of oils and concentrates examined in the present work. Values lower than this might be accounted for by the presence of biologically inactive material showing selective absorption and chromogenic power; but values significantly higher suggest the existence of a biologically active material without selective absorption or chromogenic power, or with these characteristics much weaker than in the vitamin C<sub>20</sub>H<sub>29</sub>OH.

One of us (J. R. E.) is indebted to the Medical Research Council for a full time personal grant.

The biological assays reported in this paper were made in the Research Department of Lever Brothers, Limited; the spectroscopic work was carried out in the Chemistry Department of Liverpool University. One of us (R. S. M.) is responsible for the statistical analysis.

<sup>1</sup> According to recent experiments in these laboratories (i) the absorption intensity of pure  $\beta$ -carotene (from grass) is to the absorption intensity of 1934 standard carotene as 100:86, and (ii) the comparative feeding values of 1934 standard carotene and 1931 standard carotene are in the ratio 1 1934 unit (0.6 $\gamma$  of 1934 carotene)=0.86 1931 unit (0.86 $\gamma$  1931 carotene). Thus by compensation of errors, 0.6 $\gamma$  pure  $\beta$ -carotene = 1 1931 unit.

# CXCIX. THE METABOLISM OF GALACTOSE.

## I. PHOSPHORYLATION DURING GALACTOSE FERMENTATION AND ITS RELATION TO THE INTERCONVERSION OF HEXOSES.

By GORDON ALLISON GRANT<sup>1</sup>.

*From the Biochemical Department, the Lister Institute, London.*

*(Received June 1st, 1935.)*

WHILST the mode of metabolism of glucose by the animal cell has been the subject of numerous investigations during the past fifty years, little has been contributed which would elucidate the path of metabolism of galactose, also a normal constituent of the mammalian organism.

The investigations of Draudt [1913] and of Fischler [1925] suggested that the liver was the site of the preliminary alterations concerned in the metabolism of galactose. Draudt found that in animals with Eck-fistulas, 79 % of orally administered galactose was excreted in the urine as compared with 4-10 % before the operation. Mann and Magath [1924] reported that the resuscitating action of this sugar when injected into dehepatised animals was very slight. Bollmann *et al.* [1935] find that though the utilisation of galactose is definitely impaired by hepatectomy, appreciable amounts appear to be metabolised even in the absence of the liver. In amounts of 0.5 g. per kg. body weight, the proportions are 30 % excreted in the urine, 30 % converted into glycogen in the liver, while the remaining 40 % seems to be metabolised by the extra-hepatic tissues.

Galactose is only converted into glycogen at a slow rate in the animal organism [Cori, 1926], and this glycogen upon hydrolysis yields not galactose but glucose [Harding *et al.*, 1934]. The hexose possesses a limited rate of utilisation which is but little influenced by the type of diet, by fasting, or by such hormones as insulin, thyroxine or adrenaline, factors powerful in affecting the assimilation of glucose and fructose [Wierzuchowski *et al.*, 1931; Harding and Grant, 1932-33]. It is of little value in preventing the onset of insulin convulsions [Macleod and Noble, 1923; Voegtlin *et al.*, 1924-25; Roe and Schwartzmann, 1932], unless fed for some time previously to the administration of the insulin [Moschini, 1924]. Even in the latter case its effect is very limited. In the normal individual [Kosterlitz, 1933; Harding and Grant, 1932-33] and in the diabetic [Roe and Schwartzmann, 1932; Kosterlitz and Wedler, 1933], an increase in the blood glucose may follow the ingestion of galactose. Pollak and Selinger [1933] claim that insulin increases the assimilation of galactose, and Pollak and Fehér [1933] suggest in explanation that a concomitant glucose metabolism improves galactose assimilation. Recently Roe and Cowgill [1935] obtained evidence of increased glucose in the blood flow from the liver of animals which were metabolising galactose. Definite increases in blood glucose were only observed after an hour from the time of galactose administration, a sufficiently long interval for

<sup>1</sup> Beit Memorial Research Fellow. A considerable portion of this investigation was carried out during the tenure of a Royal Society of Canada Research Fellowship.

glycogen formation to be in active progress. Moreover, in those experiments with well-fed animals, increases in blood glucose may easily be attributed to glycogenolysis of preformed glycogen. These investigators also found little evidence of the metabolism of galactose by the brain, as judged by the absence of a well-marked arterial-venous difference during the galactaemia. Ashford [1933] has obtained evidence of the production of lactic acid from galactose by brain tissue. It is known that galactose is rapidly changed into its intermediary metabolites since, when orally administered in moderate amounts, it disappears from the tissues, as free sugar, within three hours from the time of its ingestion [Harding *et al.*, 1934]. Small rises take place in the glucose of the tissues during galactose metabolism but these are too small to be interpreted, by themselves, as evidence of a direct galactose  $\rightarrow$  glucose conversion.

Galactose is apparently metabolised in two ways by the animal organism, a portion being slowly oxidised by the tissue cells generally and the remainder converted into glycogen in the liver and subsequently utilised as glucose. No investigations yet reported offer definite evidence of an immediate direct conversion of galactose  $\rightarrow$  glucose in the living tissues, under conditions which would preclude previous formation of glycogen as the precursor of the glucose.

*The metabolism of galactose by the yeast cell.*

The yeast cell was chosen as perhaps offering the simplest method of approach to the problem of the mode of metabolism of galactose. The striking correlation between the carbohydrate metabolism of muscle and yeast is too well known to require further comment. Numerous researches have emphasised the importance of phosphorylation in the intermediary metabolism of glucose, fructose and mannose by the yeast cell, but the question of its relation to galactose metabolism has received comparatively little attention.

Previous researches have established the fact that yeasts which normally possess only slight ability to ferment galactose can be adapted, by repeated culturing, to ferment this hexose with greatly increased velocity [see Lippmann, 1884; Dienert, 1900; Armstrong, 1905; Slator, 1908]. It has been suggested that the process of adaptation only occurs during active production of new cells [Söhngen and Coolhaas, 1925; Euler and Nilsson, 1925].

Harden and Norris [1910] found that a fermenting mixture of yeast-juice (from an adapted yeast) and galactose reacted with added phosphate in a similar manner to ordinary yeast-juice and glucose, though a much longer time was necessary. The rate of  $\text{CO}_2$  formation was accelerated, an extra amount of  $\text{CO}_2$  equivalent to the phosphate added was evolved and the rate then again became normal. The phosphate was converted into an organic form not precipitable by magnesium citrate mixture. Later Nilsson [1930] returned to the problem and was able to isolate from the products of the fermentation of galactose by a sample of dried adapted yeast, a diphosphoric ester which in its elementary analysis and specific rotation closely resembled the hexosediphosphate formed during the fermentation of glucose, fructose and mannose. He also obtained a monophosphate fraction which in its impure state had a specific rotation much higher than that of the Robison ester formed in glucose fermentations. Moreover, an attempt to purify it further by crystallisation of its brucine salt was unsuccessful. Whether the ester was a derivative of glucose or of galactose was not investigated.

In the present investigation, additional evidence has been produced that the diphosphate formed during the fermentation of galactose by various preparations of a yeast adapted to ferment this sugar, is the 1:6-diphosphofructofuranose.

From the monophosphate fraction trehalosemonophosphate has been isolated. There was no evidence of the occurrence of a galactosephosphoric ester. The polysaccharides built up during the metabolism of galactose yield upon hydrolysis, not galactose but almost entirely the normally fermentable sugars, glucose, fructose and mannose.

Synthetic galactose-6-phosphate was not fermented by an active juice from the adapted yeast.

## EXPERIMENTAL.

### ADAPTATION OF YEASTS TO FERMENT GALACTOSE.

A re-investigation of conditions favourable for the adaptation of certain yeasts to ferment galactose with increased velocity has been made. It was found impossible to obtain an active preparation with English brewer's top yeast using Nilsson's method [1930] of bulk adaptation. Aerobic growth on galactose-, glucose-, or hydrolysed lactose-agar flats was found unsatisfactory. *S. marzianus* was tried, but was found to be a slow grower and poor fermenter, even after several months' adaptation.

Repeated subculturing for several months of either English brewer's top yeast, or Froberg bottom yeast, in a medium of 3 % galactose\* in yeast extract + 0.6 %  $\text{KH}_2\text{PO}_4$  proved satisfactory. Such adapted yeasts fermented galactose at 80–100 % the rate for glucose. The most active preparations were obtained when the crop was removed 3–4 days from the time of inoculation. The yield of yeast varied from 8 to 10 g. per litre of medium. Varying the  $p_{\text{H}}$  between 4 and 6 had no effect upon the growth or fermentative powers of the yeast.

### FERMENTATION OF GALACTOSE BY PREPARATIONS OF THE ADAPTED YEAST.

For the investigation of the phosphorylated products formed during the fermentation of galactose, three preparations were employed, (a) fresh yeast in the presence of toluene, (b) yeast-juice, (c) dried yeast. At the beginning of the fermentation, or at appropriate intervals during its course, inorganic phosphate was added (0.5 M  $\text{K}_2\text{HPO}_4$  or  $\text{Na}_2\text{HPO}_4$ † in M galactose solution) and the rate of esterification was followed by estimating the inorganic phosphate at intervals; the rate of formation of  $\text{CO}_2$  was also measured.

The general method of Robison and Morgan [1930] was used for the isolation and separation of the neutral barium salts of the phosphoric esters formed. The crude diphosphate, precipitated by adjusting the  $p_{\text{H}}$  to 8.4 with hot concentrated baryta, was purified by repeated precipitations of its acid salt with four volumes of 96 % alcohol.

The basic lead salt of the crude monophosphate was decomposed with sulphuric acid and converted into the neutral barium salt. The small amounts of diphosphate still remaining were separated by extracting this monophosphate fraction with 10 parts of 10 % alcohol, filtering and precipitating the monophosphate (soluble B) with 2.5 volumes of 96 % alcohol.

Table I shows: the type of preparation used, the period, total  $\text{CO}_2$  production and the total amount of phosphate and sugar added in the different fermentations.

\* Kerfoot's second quality galactose, which contained some glucose was used.

† Analytical reagent, since commercial grades may contain sufficient fluoride to inhibit fermentation.

† Diphasphate fraction includes the organic P precipitated as insoluble barium salt in 10 % alcohol at  $pH$  8-4. It may contain phosphoglycerates. The monophosphate fraction represents the organic P remaining in the filtrate from the above separation. It includes slight amounts of diphasphate, as well as organic P not precipitable by basic lead acetate.

‡ Glucose millimols.

§ 8 millimols. ester P added in this fermentation. The actual amount of diphasphate (1-8 millimols.) is the same as that found in the control fermentation (10, b); 87-5 % of the added galactose-6-phosphate was recovered from the protein-free filtrate of the fermentation mixture.

In the earlier experiments (1-8) attention was chiefly directed towards obtaining the maximum amount of fermenting complex and in certain instances (Exps. 4-8) resort was had to a second pressing of the yeast, after regrounding the yeast marc with a small quantity of water. This procedure had the disadvantage of introducing extra amounts of yeast polysaccharides into the juice. For this reason, the yeast juice from a single pressing was used in Exps. 9 (a-d) and 10 (a-d), and suitable control fermentations (autofermentation alone and in the presence of added phosphate) were carried out under conditions similar to those for the galactose fermentations. Exp. 11 (a-d) shows a similar series of fermentations with a sample of the air-dried (25°) adapted yeast.

These yeast preparations fermented glucose rapidly giving a well-defined phosphate rate. They gave much lower rates of fermentation and phosphorylation with galactose but these rates were considerably higher than those attributable to the autofermentation, alone or in the presence of added phosphate

(Figs. 1, 2). Thus, phosphoric esters accumulate during the fermentation of galactose in much larger amounts than can be derived from the reserve polysaccharides in the yeast preparation used.

Fig. 1.

#### THE PROPERTIES OF SYNTHETIC GALACTOSEMONOPHOSPHORIC ESTER.

From the nature of the hexosemonophosphates formed during the fermentation of glucose, fructose or mannose it might be inferred that, if a galactose-phosphate is formed, the phosphate group will enter position 6 in the galactose molecule. A galactosemonophosphoric ester has been prepared by Levene and Raymond [1931] by the phosphorylation of diacetonegalactose and subsequent removal of the acetone groups. Its method of preparation and specific rotation were considered by Levene and Raymond to suggest that the synthetic mono-

phosphate obtained was galactose-6-phosphate. This ester has been synthesised in the present research and a further study of its properties made. In Table VI the analytical values of this ester are compared with those for the known natural hexosemonophosphoric esters. Its specific rotation is in good agreement with that previously reported by the above investigators. The Hagedorn-Jensen (H. J.) value for the galactosemonophosphate is much lower than that of glucose-6-phosphate in agreement with the fact that galactose itself possesses only 73 % of the reducing value of glucose towards this reagent. The sugar obtained by hydrolysis of the ester with purified bone phosphatase was identified as galactose.

*Hydrolysis by N HCl at 100°.* The rate of hydrolysis of the free ester in acid solution is shown in Table II. It is hydrolysed more rapidly than glucose-, or mannose-, but less rapidly than fructose-6-phosphate [Robison, 1932].

Table II. *Hydrolysis of synthetic galactosemonophosphoric ester (0.01 M) in N HCl at 100°.*

Time hours	Hydrolysis %	$k \times 10^3$

3	14.6	0.32	
5	23.3	0.38	
8	35.7	0.42	
11	44.8	0.37	
23	73.1	0.43	
58	94.2	0.32	Average 0.38

*Phenylosazone.* Synthetic galactosemonophosphoric ester when heated with phenylhydrazine in acetic acid solution, yielded a phospho-osazone which crystallised in small rosettes. (P, 5.52 %;  $C_{24}H_{31}O_7N_6P$  requires 5.69 %.) It was recrystallised twice from boiling alcohol to which an equal volume of boiling chloroform was added, the solution being then left at 0° for 24 hours; m.p. 135–137°. The formation of a phospho-osazone precluded the possibility of the phosphate being attached to carbon atom 1 or 2 of the hexose molecule.

*Formation of an insoluble methylphenylhydrazone.* The galactosemonophosphoric acid formed an insoluble methylphenylhydrazone when added to a solution of methylphenylhydrazine in glacial acetic acid at 0°. Crystallisation began in less than an hour and was completed in three hours. The hydrazone, recrystallised three times from 80 % aqueous alcohol, yielded colourless needle-shaped crystals; m.p. 134–136° (corr.; temperature rise 6–8° per minute). (Found, P, 6.34, 6.43 %;  $C_{20}H_{31}O_6N_4P$  requires 6.38 %.) By decomposition of the hydrazone with benzaldehyde at room temperature the galactosemonophosphate was regenerated and isolated as the neutral barium salt.

Galactosemonophosphate very closely resembles glucosemonophosphate in the solubility of its neutral barium, lead and basic lead salts. The brucine salt crystallises readily from its aqueous alcohol solution in elongated hexagonal plates.

The separation of a galactosemonophosphate from the other esters (glucose-, fructose-, and mannose-6-monophosphate and trehalosemonophosphate) which might occur in the soluble B fractions of a galactose fermentation presents a problem of considerable difficulty. The separation of the Robison ester into glucose- and fructose-monophosphates was only attained after a prolonged fractional crystallisation of the brucine salts [Robison and King, 1931].

The formation of the insoluble phosphomethylphenylhydrazone is therefore a valuable method for the detection of small amounts of galactosephosphoric esters.

*The fermentation of galactose-6-phosphate.* In Exps. 10, *a-d*, the fourth fermentation (10, *d*) is that of the potassium salt of the synthetic galactosemonophosphate, equimolar with the galactose in the galactose fermentation of the same series (8 millimols). The results obtained indicated that the galactose-6-phosphate was not readily fermentable in conditions in which an active fermentation of galactose was observed. (Table I.)

The rate of fermentation of the ester (in the presence of added phosphate) was not greater than that of the autofermentation under similar conditions (Fig. 2). The galactosemonophosphate was not converted into a diphosphate but was recovered unchanged in the monophosphate fraction (Tables III and VI). No evidence was obtained of the presence of a phosphohexokinase capable of converting the galactose-6-phosphate (Table VI) into an equilibrium mixture of aldose  $\rightleftharpoons$  ketose esters, which would have a considerably decreased iodine value (28 %) and a much higher Selivanoff value (6 %). This change readily takes place with the monophosphates of the normally fermentable sugars, glucose, fructose and mannose.

#### THE NATURE OF THE PHOSPHORIC ESTERS ACCUMULATING DURING THE FERMENTATION OF GALACTOSE.

##### *The hexosediphosphate.*

It has been shown that the same hexosediphosphate is formed, whether the sugar undergoing fermentation by yeast preparations is glucose, fructose or mannose [Harden and Young, 1908; Young, 1909]. To this compound the constitution 1:6-diphosphofructofuranose has been ascribed [Morgan and Robison, 1928; Robison and King, 1931; Levene and Raymond, 1928; 1931; Morgan, 1929].

The general analytical values for the neutral barium salts of the diphosphates formed in the galactose fermentations (Exps. 1; 2-8; 9, *a-d*; 10, *a-d*), are given in Table III.

Table III. *Analyses of the neutral barium salts of the diphosphoric esters formed during the fermentation of galactose.*

\* As acid barium salt.

† Determined with the addition of 0.5 ml. 0.5*N* NaOH.

‡ In acid solution.

§ Macleod and Robison [1933].

In Exps. 1 and 2-8 the diphosphates were especially purified by seven reprecipitations of the acid barium salts (Macfarlane and Robison, unpublished results). The analytical values for these purified samples are in excellent agreement with the analysis of 1:6-diphosphofructofuranose.

Exps. 9 and 10 indicate that the amounts of diphosphate accumulating during the fermentation of the galactose are much in excess of that attributable to the autofermentation of the polysaccharides in the yeast preparations used. This has also been found true for the fermentation with dried yeast (Exps. 11, *a-d*, Table I) where the galactose fermentation (11, *c*) yielded 2.0 g. of the acid salt as compared with 0.5 g. and 0.7 g. for the autofermentation alone (11, *a*) and in the presence of added phosphate (11, *b*) respectively.

*Osazone formation.* The phospho-osazone (P, 5.50 %;  $C_{24}H_{31}O_7N_6P$  requires, P, 5.68 %) melted at 153-153.5°; a mixture of the osazone with that prepared from a sample of 1:6-diphosphofructofuranose melted at the same temperature. The mutarotation of the osazone in alcohol-pyridine agrees closely with that found for the osazone of glucosemonophosphate (Table IV).

\* Macleod and Robison [1933].

These results show conclusively that the diphosphate formed when galactose is the sugar fermented is the same as that formed during the fermentation of glucose, fructose and mannose, namely 1:6-diphosphofructofuranose. The ester constitutes the major portion of the phosphorylated products and is found in amounts considerably in excess of those which can be attributed to the yeast polysaccharides.

*The monophosphoric esters.*

The amounts of the monophosphate fractions ("soluble B") isolated from the galactose fermentations and the analyses of the neutral barium salts are shown in Table VI.

Table VI. *Analyses of the neutral barium salts of the soluble B fractions obtained in the fermentations.*

<sup>4</sup> Tankó and Robison [1935].

\* The galactosemonophosphate recovered after two basic lead precipitations; the amount of the galactose ester added as potassium salt was equivalent to 3.1 g. neutral barium salt.

In Exps. 9, 10 and 11, additional data are presented to indicate the amounts and nature of the soluble B fractions produced during the autofermentation alone and in the presence of added phosphate. The composition of this fraction when glucose is the sugar fermented is recorded in Exps. 9 (d) and 11 (d).

The data given for Exps. 9–11 indicate the real source of the difficulty in obtaining a hexosemonophosphate (P, 7.84 %) from the "soluble B" fraction of the galactose fermentations. In all cases this fraction represents a relatively small portion of the total esterified phosphorus and is seriously contaminated by concomitant impurities introduced by the yeast.

The latter material has a high nitrogen content, a high iodine value, is low in P and usually possesses a negative rotation.

*Isolation of trehalosemonophosphate.* Where the low P content of the monophosphate fraction occurred together with a high dextrorotation, trehalosemonophosphate was identified. It was separated by crystallisation from the aqueous alcoholic (10–20 %) solution of the monophosphate fraction. Under these conditions the trehalosemonophosphate crystallises as the sparingly soluble barium salt [Robison and Morgan, 1930]. The amounts are shown in Table VI.

Several recrystallisations of the crude salt yielded in each case pure crystalline trehalosemonophosphate as judged by the analyses of the neutral barium salt. [P, 5.57 %;  $[\alpha]_{5461}^{20} + 132^\circ$  for the anhydrous salt; no reducing power (H.J. and iodine) or Selivanoff value.] However, the whole of the ester was not removed from the monophosphate fractions by the above separations.

In Exps. 9 (*a-d*), the amounts of trehalosemonophosphate isolated from the glucose and galactose fermentations (*c, d*) were far in excess of those which could be attributed to the autofermentations (*a, b*) of the yeast preparation used. The laevorotatory "soluble B" fractions obtained from the autofermentation experiments did, however, contain detectable amounts of this ester.

Preparations from the unadapted yeast also possessed the mechanism for the synthesis of this ester from the normally fermentable sugars, glucose, fructose and mannose. The formation of this diglucosemonophosphate during the fermentation of galactose by preparations of the adapted yeast is of particular interest in view of the interconversion of hexoses involved.

*Further examination of the residual soluble B fractions.* After the removal of the trehalosemonophosphate, three methods were employed to effect a separation of the remaining hexosemonophosphoric esters in the soluble B fractions.

In the first method the monophosphates were precipitated from their solutions in aqueous alcohol (10 %) as the neutral lead salts [Robison, 1922]. The analyses of the regenerated neutral barium salts for some of the experiments are given in Table VII. A certain amount of purification was achieved, for

<sup>1</sup> Methylphenylhydrazine test negative in all cases.

the P content approximates more closely to that required for a hexosemonophosphate.

It was also found possible to effect a purification of the soluble B fractions by fractionation in alcohol of their acid barium salts. The monophosphate fractions were obtained at  $p_H$  3.6 by increasing the alcohol content from 40–70 %. The analysis of one of these intermediate fractions is given for Exp. 7 and also its further separation into trehalosemonophosphate and a hexosemonophosphate fraction (Table VII, *b*, *b'*). In each case only small amounts of the hexosemonophosphates were obtained by either of the above methods.

*The methylphenylhydrazine test.* These small amounts of hexosemonophosphates were treated with a solution of methylphenylhydrazine in acetic acid, but there was no separation of an insoluble methylphenylhydrazone. The crude soluble B fractions were also subjected to this test but negative results were obtained in every case offering additional evidence of the absence of phosphoric esters of galactose from the phosphorylated products isolated from the fermentations.

The residual monophosphoric ester of the glucose fermentation (10*d'*) after removal of the trehalosemonophosphate possesses the general properties of the Robison ester though still contaminated with a little trehalosemonophosphate, as shown by the higher specific rotation. (See Table VI.)

The above results support the view that the monophosphoric esters which accumulate during the fermentation of galactose by preparations of adapted yeast are not the phosphoric esters of galactose, but those common to the fermentation of glucose, fructose and mannose. Trehalosemonophosphate has been definitely obtained, together with smaller amounts of material which resembles a hexosemonophosphate, yields a negative methylphenylhydrazine test and corresponds in its general analysis with the Robison ester found in the glucose fermentation.

*Fermentation of galactose by dried yeast at 37°.* Phenomenal yields of mannose-6-phosphate are obtained during the fermentation of mannose by dried yeast, if the temperature is 37°. This occurs only with dried yeast and does not result with glucose or fructose [Jephcott and Robison, 1933]. For this reason the fermentation of galactose by dried yeast at 37° was investigated in an attempt to increase the yield of monophosphate. This proved unsuccessful, the normal ratio of diphosphate to monophosphate being obtained. Similar results were obtained with fresh yeast + toluene at 37°. The monophosphate fraction isolated possessed a lower rotation suggesting that less trehalosemonophosphate was formed at the higher temperature of fermentation.

#### THE POLYSACCHARIDES SYNTHESISED DURING THE METABOLISM OF GALACTOSE BY THE LIVING YEAST CELL.

The sugar polymerides built up when the adapted yeast was grown upon galactose as the sole source of carbohydrate offered additional evidence of the changes involved during the metabolism of this hexose.

*Method of preparation.* The yeast (69 g. moist yeast) obtained after three days' growth in a medium of yeast extract *plus* phosphate containing 4 % galactose, was washed free from reducing substances. It was then autoclaved for 30 minutes at 120° in 400 ml. of *N*/3 KOH. The insoluble residue ("insoluble polysaccharide") was filtered off and dried *in vacuo* over  $H_2SO_4$ , after several washings with 96 %, followed by absolute alcohol (5.31 g.; reducing power (H.J.) 0.2 %).

The "soluble polysaccharide" was obtained by precipitating the above

filtrate with three volumes of alcohol. It was further purified by two reprecipitations. (3.11 g.;  $[\alpha]_{D461}^{20} + 132^\circ$ ; H.J. 0.2 %.)

*Hydrolysis of the polysaccharide fractions.* 1 g. portions of the two fractions were hydrolysed for 5 hours in  $N H_2SO_4$  at  $100^\circ$ . The hydrolysates were brought with baryta to  $p_H$  6 and the filtrates and washings concentrated to a small volume, under reduced pressure, at a temperature of  $40-50^\circ$ . Final concentration to syrups was carried out at room temperature *in vacuo* over  $H_2SO_4$ .

*Nature of the sugars in the above hydrolysates.* The procedure of Harding and Grant [1931-32] was used to estimate the "fermentable sugar" (glucose, fructose and mannose) and galactose content of the hydrolysates from the soluble and insoluble polysaccharide fractions. The mannose was estimated as insoluble phenylhydrazone; the fructose by the Selivanoff value in excess of that developed for an amount of glucose equivalent to the reducing power of the syrups.

Mannosephenylhydrazone was obtained only from the hydrolysate of the "soluble polysaccharide" fraction, M.P.  $200-201^\circ$ ; a sample mixed with pure mannosephenylhydrazone melted at the same temperature.

Galactose, if present, could be isolated as the insoluble methylphenylhydrazone. The hydrolysate from the "soluble polysaccharide" yielded an insoluble methylphenylhydrazone, not, however, that of galactose but of mannose which also forms an insoluble hydrazone in the concentrations present in the hydrolysate; M.P.  $179-180^\circ$ ; a sample mixed with pure mannosemethylphenylhydrazone melted at the same temperature; while a sample mixed with galactosemethylphenylhydrazone (M.P.  $188-190^\circ$ ) melted at a much lower temperature,  $170-172^\circ$ .

The osazone formed from the hydrolysates of both the soluble and insoluble polysaccharide fractions was almost entirely glucosazone. The combined results are summarised in Table VIII.

Table VIII. *Nature of the hexoses in the hydrolysates from the adapted yeast polysaccharides.*

Hydrolysate from 1 g. polysaccharide	% of the total hydrolysate as				Residual reduction (as glucose)
	Glucose	Fructose	Mannose	Galactose	
Insoluble polysaccharide	95.5	3	0	0	1.4
Soluble polysaccharide	77	3.3	16	1.8 (?)	1.9

The polysaccharides synthesised by the adapted yeast grown on galactose as the only carbohydrate, and isolated in the above manner, gave upon hydrolysis only the normally fermentable sugars, mainly glucose and mannose, with traces of fructose. Galactose was not found in definitely recognisable quantities by either the yeast analysis or the methylphenylhydrazine test. In this connection the detection of very small amounts of galactose, only demonstrable by indirect methods is of doubtful value as evidence of a galactose-containing polysaccharide in view of the possible contamination of the normally occurring polysaccharides by strongly adsorbed galactolipins (see recent findings of Heidelberg and Menzel [1935] upon lipo-carbohydrate complexes).

## DISCUSSION.

The specific mechanism developed in certain yeasts during the process of adaptation on galactose and required for the fermentation of this sugar is largely, though not wholly, destroyed when the adapted yeast is treated with toluene, or dried, or in the preparation of a cell-free juice. The slow rate of fermentation of galactose by such yeast preparations, compared with that of glucose, contrasts strikingly with the equal rates of fermentation of these two sugars by the living yeast.

During the fermentation of galactose, and of glucose, by these preparations of adapted yeast a concomitant phosphorylation takes place. The phosphorylated products which accumulate during the fermentation of galactose are not the esters of this sugar but of glucose and fructose. A hexosediphosphoric ester constitutes the major portion of the esterified phosphate and has been shown by a detailed study of its properties to be identical with the ester produced from glucose, fructose or mannose, namely 1:6-diphosphofructofuranose. From the monophosphate fraction it was possible to isolate the diglucose ester, trehalosemonophosphate, together with small amounts of a monophosphate closely resembling in its properties the Robison ester.

In an effort to detect any small amounts of galactosephosphate which might be present, the methylphenylhydrazine test was applied to the monophosphate fractions obtained in the fermentation of galactose, since it was shown that the synthetic galactose-6-phosphate forms an insoluble methylphenylhydrazone. The failure to obtain any evidence by this test of the presence of galactose-6-phosphate coupled with the non-fermentability of this ester by an active preparation of the adapted yeast, offers strong evidence that this galactosemonophosphate is not an intermediate product of the fermentation process. If any other galactose ester which gives an insoluble methylphenylhydrazone is formed it must undergo subsequent transformation at such a rate as to preclude its accumulation.

The living yeast cell continues to build up the same polysaccharides when galactose is the sole carbohydrate metabolised as when the carbohydrate is glucose. The polysaccharides produced are polymerides chiefly of glucose, and to a lesser extent of mannose and fructose. Moreover, 1:6-diphosphofructofuranose is the chief ester formed during the fermentation of the polysaccharides occurring in preparations of the adapted yeast.

The nature of the mechanism for this important physiological transformation by which the adapted yeast converts galactose into derivatives of glucose, fructose and mannose remains unknown. It may be that a direct galactose  $\rightarrow$  glucose conversion takes place and that the latter sugar is then metabolised in its usual manner. The nature of the hexosediphosphoric esters found during the fermentation of galactose, and of the polysaccharides synthesised during the metabolism of the sugar by the living yeast cell, are in agreement with such a view. The appearance of derivatives of fructose and mannose can easily be accounted for by the action of the enzyme phosphohexokinase which is present in the yeast, and which can convert glucose-6-phosphate into an equilibrium mixture of the aldose-ketose esters of the three sugars, glucose, fructose and mannose [Martland and Robison, 1929; Lohmann, 1933; Macleod and Robison, 1933]. As previously mentioned a monophosphate fraction closely resembling this equilibrium mixture (the Robison ester) was obtained during the fermentation of galactose. Subsequent phosphorylation of the Robison ester occurring during its fermentation

by yeast preparations may result in the formation of the 1:6-diphosphofructofuranose [Meyerhof and Lohmann, 1927; Euler and Myrbäck, 1928; Harden and Robison, 1932].

Robinson [1927] has introduced an interesting theory to account for the changes occurring during the conversion of one sugar to another. He suggested that a Walden inversion might take place during the dephosphorylation of a 4-phosphohexose, producing glucose from galactose or *vice versa*. According to such a view the interconversion of the hexoses occurring naturally is conditioned by the enzymic hydrolysis of the phosphoric esters of the hexoses concerned. Mathers and Robertson [1933] and Robertson and Oldham [1934] have found that such inversions take place during the alkaline hydrolysis of certain synthetic sugar esters having two adjacent OH groups in the sugar molecule both esterified. It is also worthy of note that in cases where a Walden inversion was proved to occur, such inversion was accompanied by anhydro-formation. These investigators suggest that anhydro-formation may be a necessary precursor of this type of inversion, which then follows as a consequence of the opening of the anhydro-ring.

If the above findings are applied to galactose, the conversion into glucose could take place upon dephosphorylation of a 3:4-galactosediphosphate. The anhydro-formation during the removal of the phosphate groups could be accompanied by a Walden inversion on one or other of the substituted carbons (3 and 4) or on both of them. In this connection a 3:4-enol of the hexosediphosphate would be of importance in the metabolism of this ester. Thus from *d*-galactose, besides *d*-glucose, variable amounts of anhydro-sugars and of *d*-sorbose, *d*-gulose and *d*-allose could result. *d*-Glucose is the only one of these sugars readily fermented by yeast.

Definite evidence has been obtained by Oldham and Robertson [1935] that the opening of a 3:4-anhydro-ring in a glucose molecule can result in the transformation of this sugar into *d*-galactose and *d*-gulose. They emphasise the relationship of these newly formed hexoses with lactose and ascorbic acid respectively.

Tankó and Robison [1935] have considered the possibility of the occurrence of natural hexoses phosphorylated in positions other than 1 and 6. These investigators find evidence which seems to point to the formation of such esters during the fractional hydrolysis of 1:6-diphosphofructofuranose by acids.

Nilsson [1930] has postulated an entirely different mechanism to account for the formation of the same diphosphate from galactose as from the normally fermentable sugars. He suggested that the galactose molecule was first decomposed into 3-carbon compounds, a procedure which would destroy the spatial specificity of the fourth carbon atom, and that these 3-carbon compounds, upon phosphorylation, could be built up into the hexosediphosphate. Meyerhof and Lohman [1934] have obtained evidence of the existence of a zymohexase in yeast and muscle preparations capable of converting triosemonophosphoric ester into fructosediphosphate. Their results suggest that dihydroxyacetone-phosphoric acid is the main triose ester to be formed *in vivo*, and it was possible to demonstrate its production from and conversion into hexosediphosphoric acid.

Cattaneo [1933] has obtained additional evidence pointing to the common path of fermentation of galactose and glucose by isolating phosphoglyceric acid from the phosphorylated products formed during the fermentation of galactose by preparations of adapted yeast in the presence of added phosphate, acetaldehyde and sodium fluoride.

Whatever the nature of the mechanism for the transformation of galactose into derivatives of glucose, fructose and mannose, it is remarkably specific for this sugar, for a yeast capable of fermenting galactose, does not possess the power readily to ferment such closely related aldose and ketose isomerides as talose and tagatose [Reichstein and Bossard, 1934].

The reverse change glucose  $\rightarrow$  galactose takes place in the active mammary gland, and it also appears to be quite specific, for in conditions in which added glucose was almost completely synthesised *in vitro* to the galactose-containing disaccharide, lactose, little evidence of synthesis from added mannose, galactose or fructose could be demonstrated. There is also a hexosephosphatase present in the active gland capable of hydrolysing the naturally occurring hexosephosphoric esters and the synthetic galactose-6-phosphate. Moreover, there is evidence of a slight synthesis of organic phosphates, by the active gland preparations, from added glucose and inorganic phosphate, provided hexokinase is also added (Grant, unpublished results).

The decision as to whether the phosphorylation occurring during the metabolism of galactose is also the primary process concerned in effecting the interconversion of hexoses observed, or whether a specific mechanism is developed for the direct interconversion of galactose  $\rightleftharpoons$  glucose prior to the phosphorylation of the latter hexose, must await the accumulation of further experimental evidence.

#### SUMMARY.

1. The specific mechanism developed in certain yeasts during the process of adaptation on galactose and required for the fermentation of this sugar, is largely destroyed when the adapted yeast is treated with toluene or dried, or in the preparation of a cell-free juice.

2. During the fermentation of galactose, and of glucose, by these preparations of adapted yeast a concomitant phosphorylation takes place. The phosphorylated compounds which accumulate during the fermentation of the galactose are not the esters of this sugar but those of glucose and fructose.

3. The major portion of the esterified phosphorus is present as 1:6-diphosphofructofuranose, while the monophosphate fraction consists of the diglucose ester, trehalosemonophosphate, and possibly smaller amounts of the typical mixed ester of fermentation, the Robison ester. No evidence was obtained of the production of a galactosephosphoric ester.

4. Synthetic galactose-6-phosphate is not readily fermented by an adapted yeast preparation capable of fermenting galactose.

5. The polysaccharides synthesised by the adapted yeast grown upon galactose as the sole carbohydrate are mainly polymerides of the normally fermentable sugars, glucose, fructose and mannose.

6. The bearing of these results upon the nature of the mechanism developed in the adapted yeast for the metabolism of galactose is discussed.

I wish to take this opportunity to express my thanks to Prof. Robert Robison, for his close supervision and valuable advice during the progress of this research. I am also indebted to the Royal Society of Canada for a Research Fellowship, during the tenure of which the earlier part of the investigation was carried out.

## CC. THE DETERMINATION OF TOTAL FATTY ACIDS IN BLOOD.

By CORBET PAGE STEWART<sup>1</sup> AND EDWARD BRUCE HENDRY.

*From the Clinical Laboratories, Royal Infirmary, Edinburgh.*

*(Received May 16th, 1935.)*

THE more important methods at present used for the estimation of fatty acid in blood are oxidimetric [Bloor, 1928] or titrimetric [Stoddart and Drury, 1929; Stewart *et al.*, 1931; Man and Gildea, 1932-33; Smith and Kik, 1933].

Bloor's method may be objected to on the ground that it depends upon the relative solubilities of the fatty acids in light petroleum. It is possible that this solvent will extract oxidisable substances other than fatty acids and cholesterol from the acidified hydrolysate, *e.g.* pigments or their hydrolytic products, bases derived from the phospholipins *etc.*, thus giving high results.

So far as the titration methods are concerned they are open to the criticism (applicable also to Bloor's method) that the extraction of lipoids from blood may be incomplete. In all cases this extraction is accomplished by adding the blood slowly to a mixture of alcohol (36 volumes) and ether (12 volumes). Man and Gildea [1932-33] claim, contrary to the generally accepted opinion, that 30 % of the lipoids may escape extraction in this way. The methods of Stoddart and Drury [1929] and of Stewart *et al.* [1931] depend upon the precipitation of the free fatty acids after hydrolysis and will therefore fail to estimate any soluble fatty acids which may be present. In considering this possible error, it must, of course, be taken into account that the acids are precipitated from sodium chloride solution, and that the presence of this salt will modify the solubility of acids actually soluble in distilled water. Man and Gildea [1932-33] have extracted the filtrate from the fatty acids by means of ether and failed to find any appreciable amount of fatty acid in the extract; since, however, they washed the ethereal extract thoroughly with water to remove mineral acid, this result is of little value. For the same reason the method of Smith and Kik [1933]—extraction of the fatty acids by means of benzene and washing the extract—cannot be accepted as estimating the hypothetical soluble fatty acids. Indeed, this method may well involve a greater loss of fatty acid than does filtration and washing of the precipitate with sodium chloride solution.

Man and Gildea have reported the further surprising result that hydrolysis with NaOH allows the recovery of only 65 % of the lecithin fatty acids, while with KOH 82 % are recovered. This is of importance, since phospholipins appear to account for most of the fatty acid present in blood [Channon and Collinson, 1929]. It is noteworthy in this connection that the exact nature of the blood phospholipins is unknown and that MacLean and MacLean [1927] state that, while lecithin is easily hydrolysed by acid or alkali, the complete hydrolysis of kephalin is much more difficult. Yasuda [1931] has found that cholesteryl esters may be hydrolysed completely by heating for 20 minutes with sodium ethoxide, and the hydrolysis of glycerides should present no difficulties.

<sup>1</sup> In receipt of a part-time grant from the Medical Research Council.

## EXPERIMENTAL.

*Extraction of lipoids from blood.* The normal procedure consists in adding 2 ml. blood slowly to about 30 ml. of the alcohol-ether mixture, raising to the boiling-point, cooling and adding more of the solvent mixture to make the total volume 50 ml. It is just possible that there may be fat-protein complexes which are not disintegrated by merely bringing the blood extract up to the boiling-point of the solvent mixture. As a variant of this procedure therefore we boiled the mixture of blood and solvent under reflux condenser for periods up to 18 hours. We found, in accordance with Man and Gildea [1932-33] that the refluxed extracts appeared to contain more fatty acid than those treated in the usual way. The increase amounted to as much as 40% in some cases and was maximum with about 5 hours' refluxing. The fatty acids are finally estimated by titration with alkali so that, actually, carboxyl groups are determined, and it is possible that the apparent increase may be due, not to an increased extraction of lipid, but to oxidation of any double bonds in unsaturated acids to extra carboxyl groups. That this is actually the case is shown by experiments in which the blood was refluxed in a continuous current of purified hydrogen. Under such conditions, oxidation is impossible, and analyses show that there is no increase in carboxyl groups due either to increased extraction of lipoids or to oxidation of unsaturated acids. Experiments in which the extract, previously separated from the protein precipitate, was refluixed, showed no increase in the titration value, but it must be remembered that when whole blood is refluxed, iron is present and may act as a catalyst for the oxidation. The results of these experiments are shown in Table I. It is noteworthy that even in presence of air, refluxing causes no increase in the lipid phosphorus.

Table I.

All values are in mg. per 100 ml. of whole blood.

Figures in columns (1) are obtained by heating the extract for 30 seconds only. Those in columns (2) are the values for the refluxed extracts.

Experimental details		Total fatty acids		"Lipoid phosphorus"	
Atmosphere	Length of time of refluxing (hours)	(1)	(2)	(1)	(2)
Air	1	282	331	—	—
Air	2	285	351	11.9	11.4
Air	3	299	421	11.7	11.4
Air	4.5	370	451	—	—
Air	5	311	405	11.6	11.8
Air	12	261	392	9.6	9.8
Air	18	279	404	12.0	12.6
Hydrogen	4	273	272	10.4	9.6
Hydrogen	4	418	415	12.0	11.9
Hydrogen	5	370	363	—	—

Since an increase of 45%, which generally occurs after 5 or more hours' boiling, could be shown gravimetrically, an attempt was made to weigh the fatty acids obtained from a comparatively large volume of blood. After the washed fatty acids had been extracted with alcohol, the solution contained varying amounts of sodium chloride depending upon how thoroughly the filter-paper had been drained. Aliquot portions of the extract were evaporated in a platinum crucible, dried in the steam-oven and weighed. Incineration of the organic matter was carried out at as low a temperature as possible in order to avoid loss of chloride by volatilisation, and after cooling the weight of the chloride was found. The difference gives the weight of fatty acids

*plus* cholesterol in both the ordinary and in the refluxed specimens. Owing to the difficulty of evaporating alcohol-water solutions containing sodium chloride and the comparatively small differences in weight, these experiments yielded no reliable results. They may be instructive, however, if large quantities of animal blood are available.

As a further control on the completeness of the alcohol-ether extraction, we carried out a series of experiments in which samples of the same blood were extracted with different solvents including 1:1 alcohol-chloroform, pure acetone, and 1:1 alcohol-light petroleum (B.P. 40–60°). While acetone, as expected, owing to the insolubility of the phospholipins in it, gave low results, it is remarkable that both alcohol-chloroform and alcohol-petroleum gave results identical with those obtained using alcohol-ether as the solvent. Such results are shown in Table II. In no case did the alternative solvent give a significantly higher value for the fatty acid than the ordinary alcohol-ether mixture, and the identity of the results with all solvents except acetone is strong evidence that the extraction is practically complete.

Table II.

All values are expressed in mg. per 100 ml. of whole blood.

	Alcohol- ether	Alcohol- chloroform	Alcohol-light petroleum	Acetone
Blood sample No. 1:				
Total fatty acids	300	303	309	232
"Lipoid phosphorus"	10.6	10.7	11.3	7.90
Total cholesterol	132	136	138	—
Free cholesterol	83	86	—	73
Blood sample No. 2:				
Total fatty acids	298	298	286	—
"Lipoid phosphorus"	11.5	11.45	11.6	—

*Hydrolysis of the extracted lipoids.* Alcoholic NaOH and sodium ethoxide are in general use for the saponification of lipoids extracted from blood. Both Stoddard and Drury [1929] and Stewart *et al.* [1931] have used the former, and the following experiments were designed to test the completeness of the saponification by this reagent. Normally, an aliquot of the alcohol-ether extract of blood is mixed with 5 ml. of *N*/10 NaOH and the mixture, after being taken down to about 1 ml. on the hot-plate, is finally evaporated to dryness in the steam-oven—care being taken to avoid prolonged overheating after the soaps are dry. Hydrolysis may be extended by the addition of 5 ml. water *plus* 5 ml. alcohol when the mixture has boiled down almost to dryness, and this process may be repeated *ad lib.* Table III shows the effect of varying numbers of such hydrolyses, compared with the result normally obtained after a single hydrolysis.

Table III.

Total fatty acids are expressed in mg. per 100 ml. of whole blood.

Case	Number of hydrolyses		
	1	2	3
Mixed blood	326	336	—
D.B.	279	—	279
Mixed blood	404	—	398
H.M.	237	229	—

It is at once obvious that there is no object in prolonging the hydrolysis beyond the ordinary time, and since at the end of each hydrolysis the alkali becomes fairly concentrated, it can safely be assumed that saponification is complete. Furthermore, it appears that so long as the fatty acids

remain in an aqueous alkaline medium, there is no tendency towards oxidation of the unsaturated acids. If the soaps be left in the steam-oven for any considerable time after they are dry, there is a large increase in the number of carboxyl groups present, as demonstrated in the volume of alkali required for their neutralisation. In an endeavour to avoid the possibility of oxidation occurring at this stage, the hydrolysate was taken down to 1 ml., the flask was filled with hydrogen and evacuated, and the soaps were dried at 70–90° on a water-bath. Control experiments by the ordinary method showed that such a modification gave definitely lower results, but this is to be ascribed to a loss of material and not to reduction in the amount of any oxidation which may have occurred in the controls. During the process of drying the soaps *in vacuo*, it is impossible to avoid frothing, and when dry, the soaps are distributed round the sides of the flask in such a manner as to prevent the action of the HCl in liberating fatty acid quantitatively. However desirable such a modification would appear, it has been found impossible to overcome the defects in such a manner as to produce a reliable routine method along these lines. When the soaps are allowed to dry for periods of 24 hours, there is a variable increase in the number of carboxyl groups, but it is usually of the order of 50–75%. Such variation is to be expected, since it will depend upon the iodine value of the fatty acids.

If care be taken to avoid oxidation of the fatty acids while drying, by removing the flasks as soon as all moisture has disappeared, duplicate analyses may be regularly obtained to within 2% by Stewart, Gaddie and Dunlop's method.

*Precipitation of the free fatty acids.* Excess of HCl used to liberate the fatty acids from the soaps appears to have little effect upon the final titration. As a routine, we have added sufficient *N*/10 HCl to make the mixture definitely acid to litmus. Even an extra 1 ml. of *N*/10 HCl, however, is without effect on the final result. In order to facilitate the filtration of the precipitated fatty acids it is advisable to add the HCl without agitation and to shake gently only after the mixture has stood for some time. Addition of the acid to the hydrolysate before complete evaporation results generally in the precipitation of the fatty acid in so finely divided a form that filtration without loss becomes almost impossible.

*The hypothetical water-soluble fatty acids.* Ordinarily the precipitated fatty acids are filtered through a fat-free filter-paper and the flask and paper are washed three times (or until the washings are neutral) with 5% NaCl. The filter-paper is then returned to the flask and extracted 4 or 5 times with boiling absolute alcohol. The combined extracts are made up to 10 ml. with alcohol, and 2 ml. of this are at once titrated with *N*/10 NaOH from a Rehberg burette, using phenolphthalein or (better) thymol blue as indicator. The extraction of the precipitated fatty acids from the paper is complete, since further extraction has been shown to give no further amount of fatty acid, and since estimation of known solutions of tripalmitin gives the correct result. There is a "blank" correction in the titration which is due in part to the amount of alkali required to change the colour of the indicator and in part to the presence of traces of acid in the alcohol. Since alcohol absorbs CO<sub>2</sub> on exposure to air, this blank titration must be made under the same conditions as the actual estimation, *i.e.* with freshly boiled alcohol.

There still remains, however, the question of the water-soluble fatty acids which are not estimated by this method. Whilst various authors consider that they constitute about 5% of the total, it is as yet unknown if they are soluble in 5% saline, and NaCl has the general effect of reducing the solubility of fatty

acids in water. In an attempt to solve this problem and eliminate a source of error, experiments have been carried out in which the fatty acids were extracted from the acidified hydrolysate by means of organic solvents,  $\text{H}_2\text{SO}_4$  being used in place of  $\text{HCl}$  for acidifying the mixture. Preliminary experiments showed that a dilute solution of  $\text{H}_2\text{SO}_4$  could be repeatedly extracted by light petroleum without the latter removing any of the mineral acid. This process could also be carried out with benzene, but not with ether. Control experiments have been carried out by extracting  $\text{H}_2\text{SO}_4$  solution, containing both phosphoric and lactic acids, with these three solvents. Phosphoric acid (from phospholipins) will, and lactic acid may, occur in the alcohol-ether hydrolysate. Extraction of 2 ml. of  $N/2$   $\text{H}_2\text{SO}_4$ , plus 0.5 ml. syrupy phosphoric acid, plus 0.5 ml. pure lactic acid, by either light petroleum or benzene yielded a "blank" exactly equal to that on boiled alcohol alone. It is therefore unnecessary to wash the light petroleum or benzene layer after extraction, and thus loss of water-soluble extracted material can be avoided. Ether is useless, even in the absence of lactic acid, for the solubility of water in it is too great and very high "blanks" are obtained.

To test the effect of extraction in place of filtration, the following procedure was adopted. One drop of an aqueous solution of phenol red was added, and the mixture was made just acid with  $N/2$   $\text{H}_2\text{SO}_4$ . The fatty acids were allowed to stand overnight and were then extracted with 5 ml. portions of light petroleum (b.p. 40–60°, redistilled over solid potassium hydroxide); 4 or 5 extractions were made. The petroleum layer was then evaporated to about 1 ml. on the hot-plate and the last traces of the solvent were removed by a current of purified hydrogen. The mixture of fatty acids and cholesterol was then thoroughly extracted with 3 ml. portions of boiling alcohol and the volume made up to 10 ml. 2 ml. of this solution were then titrated with  $N/10$   $\text{NaOH}$  in the usual manner. Typical results showing a comparison between this modification and Stewart, Gaddie and Dunlop's method are given in Table IV.

Table IV.

All results are expressed in mg. per 100 ml. whole blood.

Case	Total fatty acids		Percentage increase of (2) over (1)
	(1) by the filtration method	(2) by the extraction method	
F 1	216, 220	225, 222	+2.5
L 1	211, 211	221, 216	+3.6
F 2	199	202	+1.5
R	221	218	-1.4
T	495	516	+4.2
F 3	245	260	+6.1
L 2	247	262	+6.1
M 1	273	286	+4.6
L 3	244	248	+1.6
M 2	245	250	+2.0
Average increase			+2.58

It is evident that extraction with light petroleum gives results which are slightly higher than those obtained by the filtration method. In all probability, this is due to the fact that the former technique will estimate all the soluble fatty acids with the possible exception of any hydroxy-acids which may be present. The extraction modification differs from Bloor's method only in the final stages—the difference between the two hydrolysing agents being negligible,

as stated above. If the fatty acids can be estimated by the titration method, they must necessarily be estimated by the oxidation procedure also; and furthermore, the former is undoubtedly preferable, since the occurrence of any oxidisable matter in the light petroleum extract, other than fatty acids and cholesterol, is of no account during the titration. This possibility is more than a mere suggestion, for, when the matter soluble in light petroleum is extracted with alcohol, some insoluble matter is always found in suspension. If this be organic, and there are indications that it is, it will seriously interfere with the chromate oxidation, but not with the titration.

It must be admitted, however, that the light petroleum extraction method followed by titration is not entirely satisfactory and, for some unknown reason, duplicates occasionally fail to agree. The cause of these failures has not been discovered, but there are sufficient comparisons with the filtration method in Table IV to show that agreement is not accidental. However, the difference between the extraction method and the filtration is so small that the latter may legitimately be accepted as substantially correct, and in our hands, at least, it provides by far the simpler and more reliable technique.

#### SUMMARY.

It has been shown that various solvent mixtures other than alcohol-ether will extract the same amount of fatty acid from blood.

The yield of fatty acids is not increased by refluxing the blood with the usual alcohol-ether mixture, but a certain amount of oxidation occurs in the process, giving an increase in the number of carboxyl groups. Refluxing does not increase the recovery of "lipoid phosphorus".

Alcoholic sodium hydroxide and sodium ethoxide are equally good hydrolysing agents, and a single hydrolysis by the former will give the maximum yield of fatty acids.

The filtration method has been compared with a method in which the fatty acids are extracted by light petroleum. It has been shown that the soluble fatty acids in blood amount to less than 3 % of the total.

The expenses of this work were partly defrayed by a grant from the Moray Fund of the University of Edinburgh.

# CCI. THE PHOSPHOLIPINS OF BLOOD.

By CORBET PAGE STEWART<sup>1</sup> AND EDWARD BRUCE HENDRY.

*From the Clinical Laboratories, Royal Infirmary, Edinburgh.*

*(Received May 16th, 1935.)*

THE phospholipins account for a very considerable fraction of the total fatty acids in blood. This, with the fact that theories of fat transport and utilisation have been based on variations in the phospholipin content of the blood, makes it very desirable to determine whether the available methods are adequate for the estimation of blood phospholipins, and also what phospholipins are present.

For the estimation of phospholipins, two main methods are available, the first elaborated by Bloor [1929], and modified by Boyd [1931], depends on the oxidation of material precipitated by acetone and magnesium chloride from an ethereal extract; the result is expressed in terms of lecithin. The second method is that of estimating the "lipoid phosphorus" by one of the various methods proposed for determining small amounts of phosphorus; this method suffers from the defects that (a) the "lipoid phosphorus"—i.e. the phosphorus in an alcohol-ether extract of blood—has been stated to contain phosphorus not derived from phospholipins, and (b) it has generally been tacitly assumed that a method suitable for the micro-estimation of inorganic phosphate will also, after incineration of the organic material, satisfactorily measure the "lipoid phosphorus", and this is by no means always the case.

In several respects a method based on the "lipoid phosphorus" is to be preferred, provided it can be shown to be reliable. One important advantage is that it makes no assumption as to the exact phospholipin present; a second is that it is both easier and quicker to carry out than the oxidative procedure. We have therefore examined in detail the steps in the estimation of the "lipoid phosphorus", and after defining the conditions for accurate estimation of this fraction of the blood phosphorus, have shown that no serious error is involved in regarding it as the phosphorus derived from phospholipins.

The convenient colorimetric methods for the estimation of phosphorus depend upon the reduction, to a blue substance, of phosphomolybdic acid, without molybdic acid being similarly affected. Of the various reducing agents suggested, that of Fiske and Subbarow [1925], 1:2:4-aminonaphtholsulphonic acid, has proved by far the most satisfactory in our hands. The production and reduction of phosphomolybdic acid depend upon a number of other factors, of which the most important seems to be the acidity of the solution during reduction. Absence of acid results in reduction of molybdate itself whilst excess of acid prevents the reduction of phosphomolybdate; and it must be remembered that removal of organic matter from the alcohol-ether extract is accomplished in an acid medium.

It is evident that in the destruction of organic matter prior to phosphorus estimation, sufficient acid must be used to keep the foot of the test-tube ( $6 \times \frac{1}{2}$  in., pyrex) covered during the process. Moreover, during that process, some acid is invariably lost by evaporation and by reduction, the amount depending upon the amount of organic matter present and the length of time of heating. The minimum of sulphuric acid which can be used without complete

<sup>1</sup> In receipt of a part-time grant from the Medical Research Council.

evaporation to dryness during the ashing is 1 ml. of 10 *N* acid, and this amount diluted to 10 ml. completely inhibits the reduction of phosphomolybdic acid in the cold, although not at 100°—*i.e.* in a boiling water-bath. From Fig. 1,

Fig. 1.

which shows the effect of varying the final concentration of acid on the apparent amount of phosphorus present, it appears that the permissible final concentration lies between 0.75 and 1.20 *N*. This, since the final volume is 10 ml., corresponds to 0.75 ml. of 10 *N* acid as the minimum which must remain after incineration. Actually, if 1.0 ml. of 10 *N* acid is used initially, the loss only approaches 25 % if the amount of organic matter present is very exceptionally large, and this quantity of acid is therefore suitable. It can be increased to 1.2 ml. with a rather greater margin of safety but not beyond that amount. To conserve acid for the incineration, it is our practice to use an aqueous solution of ammonium molybdate in place of the more usual molybdic acid-sulphuric acid mixture, and these figures for the permissible amount of acid are based on this practice.

The destruction of organic matter by heating with sulphuric acid and perhydrol has been criticised by Baumann [1924] and others on the ground that phosphoric acid may be lost by volatilisation and by conversion into metaphosphoric acid. In actual practice these criticisms seem to be unwarranted, for standard amounts of phosphate have been heated for several times the normal period and with addition of several times the normal amount of perhydrol (to destroy excessive amounts of added organic matter) without any appreciable loss of phosphorus.

The amount of molybdate is of some importance. There must be sufficient to combine with the largest amount of phosphorus likely to be encountered, but excess tends to cause development of the blue colour even in absence of phosphate. It is true that "standard" and "unknown" are similarly treated, but a colour due to the reagent seriously diminishes the range of colour variation over which proportionality of colour and phosphorus concentration exists. Under our conditions, 0.5 ml. of 2.5 % ammonium molybdate is satisfactory, and the maximum allowable is 0.75 ml.

Excess of reducing agent (aminonaphtholsulphonic acid) up to five times the normal amount introduces no error but produces no advantage.

The colour under our conditions of acidity is not developed in the cold, but in the boiling water-bath it reaches 96 % of its maximum depth in 5 minutes, is fully developed in 10 minutes and is not altered by further heating up to a total of 25 minutes. Thereafter it changes to a brown which is useless for colorimetric purposes.

The method as finally adopted differs only in details from those already published, but the details are so important that a full description is warranted here. Only by attention to them can accurate and reproducible results be obtained, though in practice the method adds the virtues of ease and rapidity.

#### *Determination of "lipoid phosphorus".*

##### *Solutions required:*

10*N* sulphuric acid, 90 ml. conc. acid added to 260 ml. water.

Merck's Perhydrol.

Standard phosphate solution, 1 ml. equivalent to 0.01 mg. P.

2.5 % aqueous solution of ammonium molybdate.

1:2:4-Aminonaphtholsulphonic acid solution, made up according to the directions of Fiske and Subbarow.

##### *Details of method:*

2 ml. of blood or plasma are run into 3:1 alcohol-ether mixture according to the method of Bloor, extracted, cooled, made up to 50 ml. and thoroughly mixed. 5 ml. of the extract are pipetted into a 6 ×  $\frac{5}{8}$  in. pyrex tube graduated at 10 ml., a glass bead is added and the solvent evaporated off. After cooling, 1 ml. of 10*N* sulphuric acid is added and the heating continued until the mixture is thoroughly charred. It is then allowed to cool and the carbon is removed by the addition of one drop of perhydrol. The acid is heated until it has distilled up as far as the 10 ml. graduation mark, care being taken to avoid excessive loss by fuming. Further charring invariably occurs at this stage, and a second drop of perhydrol is required. The acid should be again distilled up as far as the mark to decompose the excess of peroxide completely.

The tube is allowed to cool and the sides are washed down with water so that the final volume is approximately 9 ml. The contents of a second tube containing 0.02 mg. phosphorus are also diluted to about the same volume. To both tubes are added 0.5 ml. of the molybdate, and 0.4 ml. of the reducing agent, and after mixing, the tubes are placed in a boiling water-bath for 10 minutes. They are then cooled in running water and the contents made up to the mark and compared.

With a method capable of estimating accurately a small amount of phosphorus in the presence of a considerable amount of organic matter, it became possible to attack the second part of the problem, and to consider whether the phosphorus present in the alcohol-ether extract of blood really affords a true measure of the phospholipins of blood. The evidence of this is necessarily indirect.

In the first place it is significant that, as in the case of total fatty acids [Stewart and Hendry, 1935], the same amount of phosphorus is extracted from blood by alcohol-ether, alcohol-chloroform and alcohol-light petroleum. Naturally less is extracted by acetone. It is further significant that refluxing the mixture of blood and solvent does not increase the amount of phosphorus extracted. These two facts suggest very definitely that the alcohol-ether mixture extracts all the phospholipins but do not reply to the criticism that other phosphorus-containing compounds may be extracted as well.

Two sets of experiments have been made to decide this latter point. In the first, various phosphorus compounds, organic and inorganic, were added in the solid state to blood in amounts vastly greater than the normal, and the alcohol-ether extractable phosphorus was then estimated in the usual way. Only in

Table I.

Results expressed in mg. "lipoid phosphorus" per 100 ml. whole blood.

	3:1 alcohol- ether	3:1 alcohol- chloroform	3:1 alcohol-light petroleum	Acetone

In the second series of experiments, the phospholipins were precipitated by the method used in Bloor's [1929] oxidimetric estimation. The alcohol-ether extract was evaporated to dryness (with a current of hydrogen in the final stages), the residue was extracted with anhydrous ether (free from peroxide), the centrifuged extract was concentrated by evaporation, and the phospholipins were precipitated by acetone and an alcoholic solution of magnesium chloride. The precipitate, washed with acetone, was extracted with moist ether to dissolve the phospholipins. The residues and washings at all stages were analysed for phosphorus with the results shown in Table III.

Table III.

"Lipoid P" of the original blood mg. per 100 ml.	P left after ether extraction mg.	P in the acetone washings mg.	P left in the $MgCl_2$ residue mg.	P in the final ether extract mg.	Percentage of the original P recovered
9.66	0.05	0.00	0.27	9.06 (94 %)	97.1
12.71	0.07	0.00	0.32	12.06 (95 %)	98.0
11.56	0.05	0.00	0.42	10.55 (91 %)	95.5
12.48	0.06	0.00	0.22	11.91 (95 %)	97.6
10.45	0.08	0.00	0.28	9.92 (95 %)	98.3
12.77	0.05	Trace	0.23	12.22 (96 %)	98.0

The original alcohol-ether phosphorus is adequately accounted for in the various residues and extracts. In all but one case, at least 94 % of the original phosphorus was recovered in the final ether extract. No appreciable loss occurs except at the stage where the purified phospholipins are extracted with moist

ether. This cannot be manipulative error, for it would not all be concentrated at this point, and 99.5 % of the total phosphorus was initially extractable with ether. The most obvious, and probably the correct, explanation lies in the assumption that decomposition has occurred to a slight extent. It is noteworthy that the precipitate, pure white at first, invariably darkens slightly on standing even when the ether used is completely peroxide-free. The 1-3 % of phosphorus which remains with the magnesium chloride cannot be recovered by increasing the number of extractions with moist ether; nor is there any insoluble phospholipin-magnesium chloride complex, since acidification does not increase the quantity of phosphorus extracted. It is noteworthy too, that repeated purification by reprecipitation with acetone and magnesium chloride involves, each time, the loss of 1-3 % of phosphorus in the residue of magnesium chloride (with a corresponding loss of fatty acids)—a fact which also points to decomposition.

Having regard to the notorious instability of the phospholipins, especially when they are in the pure state, it is almost certain that after precipitation there is slight decomposition to inorganic phosphorus, or some other ether-insoluble fraction, with loss of the corresponding amount of fatty acids in the acetone washings. Even without such an assumption, 95 % of the original "lipoid phosphorus" has turned out to be true lipin phosphorus, and there are indications, as noted above, that the percentage is even greater. It will be seen in the above table that a small loss (2-3 %) arises from the difficulties of manipulation, and this also is probably true lipin phosphorus.

It seems justifiable to deduce from these experiments that the use of "lipoid phosphorus" estimations as a means of determining the phospholipins of blood involves a maximum error of 5 %, and that in all probability the error is much less than that, and is, in fact, within the limits to be expected of a micro-chemical procedure.

The method of precipitation by acetone and magnesium chloride provided a means of investigating the nature of the blood phospholipins, since it was possible to estimate not only the phosphorus but also the fatty acids in the ether-soluble matter of the precipitate. The presence of magnesium introduced a certain difficulty, however, since the ethereal extract of the precipitate apparently contained a magnesium complex, which, after hydrolysis, yielded a small but appreciable amount of magnesium soaps. As these are not attacked by the addition of dilute hydrochloric acid, the results of fatty acid estimations may thus be too low. After unsuccessful attempts to remove the magnesium by ammoniacal sodium phosphate or by 8-hydroxyquinoline, it was found that a white gelatinous precipitate which formed early during the hydrolysis of the fats consisted of magnesium hydroxide and could be removed by centrifuging without loss of fatty acid. After the completion of the hydrolysis, acidification and extraction of fatty acids, there was no remaining precipitate of magnesium soaps. Attempts to dispense with magnesium chloride resulted in a considerable loss of material as did replacement of that salt by alcoholic solutions of lithium chloride or cadmium chloride.

Experiments on these lines gave the rather surprising result that the ratio of fatty acid molecules to phosphorus atoms is approximately 1.5:1.0. For lecithin and kephalin the ratio is 2:1, and for sphingomyelin, 1:1. The same ratio was obtained when magnesium chloride was omitted and the phospholipins were precipitated by acetone alone, although here there was an appreciable loss of material. Purification of the material by reprecipitation with acetone and magnesium chloride does not affect the ratio.

Table IV. *Table showing the equivalent of 1 mg. of "lipoid phosphorus" in terms of mg. of fatty acids in the phospholipins of blood.*

	Equivalent found	Notes
Magnesium not removed	13.24	Average of 10 analyses

Magnesium removed as phosphate	13.07	Average of 4 analyses
Magnesium removed as hydroxide	12.88	Average of 3 analyses
	13.12	Average of 19 analyses

It seems, therefore, that the phospholipins of blood must consist approximately of 50 % sphingomyelin and 50 % of a mixture of lecithins and kephalins. The presence of some kephalin is indicated by the fact that the purified material is only partly soluble in dry ether.

This deduction would be modified if the presence of galactosides were demonstrated since they contain fatty acids but no phosphorus. Their presence in the purified material would mean that sphingomyelin formed more than 50 % of the mixture, while lecithin and kephalin accounted for correspondingly less. We believe, however, that galactosides are not present in the material precipitated by acetone and magnesium chloride. It is true that this material, extracted by water, gives a positive Molisch reaction (of intensity varying in different samples) and shows the presence of "sugar" which can be estimated by the Hagodorn-Jensen method. Purification by repeated reprecipitation and elution with ether, however, completely abolishes the Molisch reaction without appreciable alteration of the fatty acid : phosphorus ratio. Elimination of galactosides by purification would result in a change in this ratio. Moreover, consideration of the delicacy of the Molisch reaction and the amounts of material concerned indicate that the repurified phospholipin fraction contains not more than 5 % of fatty acid, at most, which could be combined with carbohydrate.

Theoretically, it should be possible to estimate the relative amounts of lecithin (and/or kephalin), sphingomyelin and galactosides by determination of the nitrogen, phosphorus and fatty acid contents of the purified material. Taking as a basis the recognised composition :

	Phosphorus atoms	Nitrogen atoms	Fatty acid residues
Lecithin and kephalin	1	1	2
Sphingomyelin	1	2	1
Galactosides	0	1	1

this procedure should give three simultaneous equations. Previous workers have found excessively high values for the nitrogen content of partly purified preparations [Channon and Collinson, 1929; MacLean, 1912] and the presence of foreign nitrogenous substances has of necessity been postulated. In our analyses, material purified by a single acetone-magnesium chloride precipitation gave values for the N:P ratio varying from 2.35 to 3.67. Calculation from the observed fatty acid:phosphorus ratio of 1.5:1 shows that the maximum value for the N:P ratio is 2.5 which occurs when lecithin (and kephalin) is absent, and sphingomyelin accounts for 66 % of the material, the remainder being galactosides. The figures for nitrogen thus point, in our analyses also, to the presence of foreign matter. Purification (which, as already stated, does not alter the relative amounts of phosphorus and fatty acids) certainly reduces the N:P ratio, but we have never found a value below 2.0 which would correspond to a mixture of 1 part of lecithin (and/or kephalin), 2 parts of sphingomyelin, and

1 part of galactosides. With the amount of material at our disposal, the carbohydrate of such a mixture should be readily detectable.

Since we failed to detect any carbohydrate in the purified material, and since the N:P ratio was very variable even in the purified specimens, it seems that the evidence from the nitrogen estimations must be regarded as unreliable, that the absence of galactosides from the purified phospholipins is most probable, and that therefore the phospholipins of blood consist essentially of a mixture of equal parts of sphingomyelin and lecithin (and/or kephalin).

#### SUMMARY.

Conditions are described for the accurate measurement of organic phosphorus by the Fiske and Subbarow method, and in particular for the determination of "lipoid phosphorus".

Evidence is advanced that the "lipoid phosphorus"—i.e. the phosphorus present in the alcohol-ether extract of blood—affords an accurate measure of the phospholipins.

In preparations of phospholipins, purified by repeated precipitation by acetone and alcoholic magnesium chloride, the ratio of fatty acid molecules to phosphorus atoms is about 1.5:1. Since the balance of evidence is against the presence of galactosides, this is interpreted as indicating that about half of the phospholipin consists of sphingomyelin and half of a mixture of lecithin and kephalin.

The expenses of this work were partly defrayed by a grant from the Moray Fund of this University, hereby gratefully acknowledged.

## CCII. THE OXIDATION OF THE FATTY ACIDS *IN VITRO*, WITH ESPECIAL REFERENCE TO THE OXIDATION OF $\beta$ -HYDROXYBUTYRIC AND ACETOACETIC ACIDS.

BY ROBERT OWEN JONES AND IDA SMEDLEY-MACLEAN.

*From the Biochemical Department, Lister Institute of Preventive Medicine.*

*(Received May 30th, 1935.)*

WE are still profoundly ignorant of the methods by which the fatty acids are oxidised in the body and of the nature of the intermediate stages of their oxidation: even in the laboratory, the effect of different conditions of oxidation has been little studied. The classic experiments of Dakin [1908] showed that when fatty acids containing six or more carbon atoms in the molecule were oxidised by heating the solutions of their ammonium salts with two molecular proportions of hydrogen dioxide for at least 2 hours on a boiling water-bath, about 10 % of the acid underwent  $\beta$ -keto-oxidation, one molecule of  $\text{CO}_2$  being split off and the corresponding methylketone formed. The lower acids were rather more completely oxidised, between 40 and 50 % of a molecular proportion of  $\text{CO}_2$  being split off from formic and propionic and about half that amount from acetic and butyric acids. The identification of propionic and later of as much as 50 % of succinic acid [Cahen and Hurtley, 1917] among the oxidation products of butyric acid showed that  $\alpha$ -,  $\beta$ - and  $\gamma$ -oxidation of butyric acid had occurred, a similar finding being later established for palmitic acid by the work of Clutterbuck and Raper [1925].

This oxidation of the fatty acids was greatly increased by adding a few drops of a cupric solution to the dioxide reaction mixture [Smedley-MacLean and Battie, 1929]; in the case of the higher fatty acids, evidence was produced that in the presence of the catalyst hydroxylation took place simultaneously at several points in the chain of carbon atoms, unsaturated fatty acids being formed and a considerable proportion of the original acid broken down to acids containing 4 or fewer carbon atoms [Smedley-MacLean and Pearce, 1934].

A quantitative study has now been made of the oxidation of the lower fatty acids by means of hydrogen dioxide and of the effect produced by the addition of the copper catalyst. The earlier experiments were carried out under similar conditions to those already recorded [Smedley-MacLean and Battie, 1929], but this method had the disadvantage that the reaction took place in a medium in which the degree of acidity constantly increased as acid products were formed: further, the concentration of hydrogen dioxide was constantly decreasing since the total amount of the dioxide was added at the beginning of the experiment.

### *Preliminary experiments.*

Preliminary experiments established that when a solution of the sodium salt of a lower fatty acid was treated with a large excess of hydrogen dioxide at 60° in the presence of a cupric salt, the acids were oxidised to  $\text{CO}_2$  in the following proportions: formic, 90 %; acetic, 30 %; propionic, 40 %; butyric, 10 %.

At 90°, from 20 to 25 % of the total carbon of butyric acid appeared as CO<sub>2</sub>, 9-14 % as succinic acid, 4-5 % as acetone, 3 % as formic acid and 3 % as aldehyde. Propionic and acetic acids were estimated as 8.5 % and a considerable proportion of the butyric acid was recovered unchanged.

The precipitates of 2:4-dinitrophenylhydrazones from the non-volatile products were separated by recrystallisation from 96 % alcohol into two substances; one, melting at 291°, was recrystallised from ethyl acetate and chloroform and satisfactorily identified by comparison with a specimen prepared from methylglyoxal.

The other after several recrystallisations from alcohol melted at 201°. (Found (microanalysis): C, 42.97, 42.74; H, 3.72, 3.67; N, 19.45, 19.10 %. Molecular weight., by Rast's method, 279. C<sub>10</sub>H<sub>10</sub>O<sub>6</sub>N<sub>4</sub> requires: C, 42.56; H, 3.55; N, 19.86 %. Mol. wt. 282.)

This hydrazone appeared therefore to be derived from a keto-derivative of butyric acid. Specimens of the corresponding hydrazones of  $\alpha$ - and  $\beta$ -ketobutyric acids and of the half aldehyde of succinic acid were prepared: these melted respectively at 201°, 65° and 103°. However, on taking a mixed melting point of the unknown substance and the hydrazone prepared from  $\alpha$ -ketobutyric acid, both melting at 201°, it was found to be 186°. Our supply of this substance was now exhausted and we were unable to explain the discrepancy. The  $\alpha$ -keto-acid used for comparison was prepared by condensing together hippuric and pyruvic acids in the presence of acetic anhydride and decomposing the resulting azlactonecarboxylic acid by heating it with HCl.

#### *Method of experiment.*

In order to work with an approximately constant concentration of H<sub>2</sub>O<sub>2</sub>, the method of experiment finally adopted was as follows. A flask heated to 90° in a water-bath was fitted with an inlet tube (for admitting CO<sub>2</sub>-free air) and with a reflux condenser connected to a series of flasks, the first of which was ice-cooled and contained water, and the remainder standard baryta. *N*/35 solution of the acid was introduced and the *p*<sub>H</sub> adjusted to 6.4 by the addition of *N*/2 NaOH solution (bromothymol blue). The final volume was made up to 200 ml. and the oxidation started by adding 6 ml. of 20 vols. H<sub>2</sub>O<sub>2</sub> solution and then, during 1 hour, hydrogen dioxide and *N*/2 sulphuric acid (or *N*/2 alkali as required) sufficient to maintain the concentration of dioxide at 0.19 % and the *p*<sub>H</sub> at 6.4. During the course of the experiment a steady current of air was drawn through the apparatus. The rates of addition are shown in Figs. 1 and 2.

The amounts of hydrogen dioxide and acid to be added at any given time were found in preliminary experiments carried out in an open flask so that samples of the solution could be removed and analysed. Every 2 or 3 minutes if the action was rapid, or less frequently if it was slow, a drop of solution was removed by the pipette and the *p*<sub>H</sub> determined using a bromothymol blue capillator; 1 ml. was also withdrawn and the hydrogen dioxide content determined by titrating with cold *N*/20 acid KMnO<sub>4</sub>. Since in some of the experiments oxidation products were present which readily reduced the cold permanganate solution, the method was frequently checked by adding 1 ml. of the solution under examination to acidulated KI solution and estimating the iodine liberated.

These determinations can be rapidly performed and the necessary amounts of the dioxide and standard alkali added at frequent intervals to the main volume of solution. The amounts required were plotted against the time and served as a guide for the amounts of these reagents to be run in during subsequent

experiments; by repeated trial the amounts necessary to maintain a constant concentration of the dioxide and a steady  $p_H$  of 6.4 were arrived at.

When the oxidation had been continued for 1 hour, 10 ml. *N* alkali were added and the flask was rapidly cooled. The dioxide was quickly decomposed and sufficient *N*/2 sulphuric acid added to make the total quantity of inorganic acid added during the experiment just equivalent to the total amount of alkali; finally air was drawn through the apparatus for 20 minutes.

In the determinations which were made with the copper catalyst, before placing the acid to be oxidised into the flask, an aqueous solution containing 6 ml. of the 6% hydrogen dioxide and 0.27 g. cupric sulphate crystals were introduced into the flask and the  $p_H$  of the solution was adjusted to 6.4 by the addition of *N*/2 NaOH; a brown precipitate formed and remained during the course of the experiment. Volatile products were removed from the reaction mixture by steam-distillation and the nature of the products in the residual solution was tested.

*Rate of decomposition of hydrogen dioxide at 0.19% concentration with and without copper catalyst.*

When a solution containing 0.19%  $H_2O_2$  adjusted to  $p_H$  6.4 was kept at 90° the concentration at the end of 1 hour was practically unchanged. If however 10 ml. of 2.73% solution of cupric sulphate crystals and 4 ml. *N*/2 alkali (the quantity found necessary by trial to bring the  $p_H$  of the mixture to 6.4) were introduced into the flask and 200 ml. of the dioxide solution then added, the copper precipitate which had formed changed to a dark brown and remained undissolved. At first, the dioxide decomposed at the rate of about 0.2 g. per minute, 3.4 ml. of the 6% dioxide being added each minute to maintain the concentration. Gradually the rate fell off probably owing to a surface change in the catalyst. The amounts of the dioxide added during 1 hour to maintain the concentration are plotted in Curve 0, Fig. 3; the rates of the decomposition of the dioxide after different intervals of time from the original formation of the cupric catalyst precipitate were obtained by ceasing to add the reagent, withdrawing 1 ml. of the mixture at intervals of 1 minute and determining its  $H_2O_2$  content.

Thus directly after the formation of the copper precipitate the original concentration of the dioxide was reduced to 40% in 3.3 minutes; samples tested after the precipitate had been formed for 4 hours, during which period hydrogen dioxide had been added to maintain the original concentration, showed that the concentration now fell to 40% in 9 minutes, the activity of the catalyst having been considerably impaired.

## RESULTS.

*Oxidation of the fatty acids in the absence of a cupric salt.*

When a solution (*N*/35) of the sodium salt of a fatty acid was heated for 1 hour under the above-described conditions, no appreciable amount of decomposition of the dioxide was detected in the presence of the following acids: formic, acetic, propionic, butyric, hexanoic,  $\beta$ -hydroxybutyric and acetoacetic. With tartaric acid it was necessary to add about 15 ml. of the dioxide solution to maintain the concentration at 0.19% during the hour's heating, an amount sufficient to oxidise the whole of the tartaric acid to  $CO_2$ . Some decomposition must however have occurred in the case of formic acid and to a less extent in the cases of propionic and of  $\beta$ -hydroxybutyric acids since the alteration in  $p_H$  showed that sodium carbonate had been formed from the salt of the acid.

These results are shown in Figs. 1 and 2; in Fig. 2 the amount of acid added to maintain the  $p_H$  at 6.4 was the measure of the sodium carbonate formed by the complete oxidation of the acid. Thus tartaric acid was completely oxidised

Fig. 1.

Fig. 2.

Figs. 1 and 2. Oxidation of fatty acids with hydrogen dioxide alone. 1, Formic acid; 2, Acetic acid; 3, Propionic acid; 4, Butyric acid; 5, Hexanoic acid; 6,  $\beta$ -Hydroxybutyric acid; 7, Acetoacetic acid; 8, Tartaric acid.

and about 40 % of the formate and less than 10 % of the propionate and hydroxybutyrate were converted into the carbonate. The amount of oxidation under the given conditions in the case of the other acids examined was insignificant.

### *Influence of the copper catalyst.*

The addition of the catalyst produced a striking increase in the amounts of acids oxidised, as measured both by the quantity of hydrogen dioxide decomposed and by the changes in the  $p_H$  of the solution.

Fig. 3.

Fig. 4.

Figs. 3 and 4. Oxidation of fatty acids with hydrogen peroxide and a cupric salt. 0, Hydrogen dioxide alone; 1, Formic acid; 2, Acetic acid; 3, Propionic acid; 4, Butyric acid; 6,  $\beta$ -Hydroxybutyric acid; 7, Acetoacetic acid; 8, Tartaric acid.

Fig. 3 shows that the dioxide was most readily decomposed in the presence of the sodium formate and tartrate, the normal rate of decomposition of the dioxide being considerably increased. Acetic, propionic, butyric and acetoacetic acids all acted as inhibitors of the normal decomposition in spite of the fact that these acids were themselves being oxidised;  $\beta$ -hydroxybutyric acid was intermediate between the two groups, the rate of decomposition of the dioxide being almost unchanged by the addition of this acid to the solution. The difference between the actions of acetoacetic and  $\beta$ -hydroxybutyric acids was marked.

Examination of Fig. 4 which represents the additions of acid necessary to maintain a constant  $p_H$  brings out the following points.

*Sodium formate and tartrate* were rapidly converted into sodium carbonate, the formate being completely oxidised within 5 and the tartrate within 10 minutes: in order to maintain the constant  $p_H$  it was necessary to add sufficient acid to neutralise the theoretical quantity of sodium carbonate obtainable by the complete oxidation of these salts. The vigorous initial reaction which occurred in both cases probably accelerated the rate of decomposition of the dioxide.

Estimations of the carbonic acid liberated confirmed the complete combustion of these acids.

*Sodium acetate, propionate and butyrate* were not completely oxidised during the 1 hour for which the experiment was continued, the proportions of sodium appearing as carbonate being respectively 59, 68 and 18%: butyric acid was very much less oxidised than either propionic or acetic acid. Since only 18% of the sodium of the butyrate had been converted into carbonate, the remaining 82% must have been present as neutral sodium salts: propionic, acetic and succinic acids were identified and a considerable proportion of unchanged butyrate. Acetone was also present; its estimation at the end of the experiment showed that 28% of the butyric acid had been transformed into acetoacetic acid, but since the acetoacetic acid and acetone themselves undergo oxidation during the course of the experiment, the amount actually converted must have been considerably larger. The high percentage of acetone is in agreement with the results of Witzemann [1918] who showed that oxidation in a neutral medium favoured the production of acetone.

*Oxidation of sodium acetoacetate and  $\beta$ -hydroxybutyrate.*

The oxidation of acetoacetic acid was carried out by Dakin [1924] who mentions that he identified acetic, glyoxylic, formic and carbonic acids as products of its oxidation. Engfeldt [1921], using  $KMnO_4$ , found acetic, glyoxylic and oxalic acids, whilst Clutterbuck and Raper [1926], who worked at ordinary

temperature with hydrogen dioxide in strongly alkaline solution, obtained a number of products of which they believed  $\alpha\beta$ -dihydroxycrotonic or  $\alpha$ -hydroxy-acetoacetic acid to be the first formed. The influence of strong alkali in producing condensation products makes it improbable that this method furnished a useful analogy for the process of combustion of the fatty acids *in vivo*.

It seemed to us of some importance to compare the course of oxidation of  $\beta$ -hydroxybutyric and acetoacetic acids and to determine whether the hydroxy-acid passes through the keto-compound during its oxidation by means of the dioxide. The conditions used were the same as those described above with the addition of the cupric salt. Experiments were therefore carried out to find how rapidly the acetoacetic acid decomposed when kept under the conditions of the experiment without the addition of the dioxide: the results are shown in Table II.

Table II. *Rate of decomposition of acetoacetic acid in aqueous solution at  $p_H$  6.4 to 7.0 at 90°.*

mg. acetone as acetoacetic acid in 10 ml. of original solution	Duration of heating mins.	mg. acetone in 10 ml. of solution after heating		
		As acetoacetic acid		
		(a) Free	(b) Found	(c) Calculated for 11.1 mg. in original solution
11.1	0	0.0	11.1	11.1
11.6	5	1.13	10.5	10.0
11.6	10	2.01	9.62	9.2
11.1	15	2.65	8.15	8.1
11.1	25	4.27	6.87	6.9
9.1	40	5.50	3.53	4.3
9.5	50	6.18	3.04	4.0

In (b), the excess acetoacetic acid was determined as in Folin's method by drawing off the acetone from the salt-saturated solution.

Under the conditions of the experiment, even at 90°, the acetoacetic acid appeared to be only slowly decomposed into acetone and  $CO_2$ .

Curves (6) and (7) in Fig. 4 show that for the first 20 minutes a steady formation of alkaline carbonate took place, indicating either the decomposition of a corresponding amount of  $\beta$ -hydroxybutyric or acetoacetic acid into neutral substance (aldehyde or acetone) and alkaline carbonate or its complete oxidation to carbonic acid. The change in the slope of the curve for the next 10 minutes shows that excess of acid was being formed to neutralise the carbonate either by oxidation of a neutral substance or from the decomposition of the original acid into two acid molecules. During the second half hour the direction of the curve indicated a steady change from the sodium salt of an organic acid to sodium carbonate. Since it was probable from these data that the maximum amounts of neutral substance were present at the end of 20 minutes, an experiment was carried out for this period, the volatile products being passed into a solution of 2:4-dinitrophenylhydrazine hydrochloride. The hydrazones from the oxidation of 1.77 g. acetoacetic and from the same amount of  $\beta$ -hydroxybutyric acid were separately collected, dried to constant weight, the melting-points determined and the products crystallised. The results indicated that a maximum of about 13 % of the hydroxybutyric and 37 % of the acetoacetic acid had been converted into acetone. In both cases the hydrazones melted between 110° and 116° and consisted mainly of acetonehydrazone with a small amount of acetaldehydehydrazone. After several recrystallisations from alcohol, 80 % acetic acid was

used as the solvent, but acetone-2:4-dinitrophenylhydrazone appears to be rapidly decomposed by this solvent, acetyldinitrophenylhydrazine melting at 197° crystallising out.

Table III shows the amounts of CO<sub>2</sub> and acetone obtained after oxidising the hydroxy- and keto-acids for 1 hour under the given conditions. Nearly twice as much CO<sub>2</sub> was formed from the hydroxybutyrate as from the acetoacetate, but the proportion of acetone obtained from the latter was very much greater. It seems permissible therefore to conclude that under the given conditions the main path of oxidation of the  $\beta$ -hydroxybutyric acid does not pass through the keto-acid.

Table III. *The oxidation of  $\beta$ -hydroxybutyric and acetoacetic acids.*

The oxidation of some possible intermediate products in the combustion of  $\beta$ -hydroxybutyric acid was investigated and the curves of the hydrogen dioxide decomposition and acidity changes were plotted. Figs. 5 and 6 represent the changes produced by the oxidation of acetone, acetic, glycollic, oxalic, malonic, lactic, pyruvic,  $\beta$ -hydroxybutyric and acetoacetic acids.

Fig. 5.

Fig. 6.

Figs. 5 and 6. Oxidation of possible intermediate products formed from acetoacetic acid and  $\beta$ -hydroxybutyric acid. 2, Acetic acid; 6,  $\beta$ -Hydroxybutyric acid; 7, Acetoacetic acid; 9, Oxalic acid; 10, Glycollic acid; 11, Acetone; 12, Lactic acid; 13, Pyruvic acid; 14, Malonic acid.

(1) The oxidation of acetone (Curve 11) was slow. Since no sodium was present in the original substance, there was no formation of alkaline carbonate and only about 35% of the acetone was converted into fatty acid during the hour. Probably a slow conversion into acetic acid was taking place: very little  $\text{CO}_2$  was evolved.

(2) Previous oxidation of the methyl group of acetic acid greatly increased the rate of further oxidation. Oxalic and glycollic acids were rapidly oxidised, as was also malonic acid (Curves 9, 10 and 14, Fig. 6).

(3) With pyruvic acid there was so rapid a development of carbonic acid that the addition of a small amount of alkali was necessary to maintain the  $p_{\text{H}}$  at 6.4. Subsequently the curve followed very much the course of that of acetic acid (Curve 13, Fig. 6).

(4) The curve for lactic acid showed a fairly rapid development of alkalinity and in these experiments a strong smell of aldehyde was noticed at the beginning of the oxidation. It seems probable that the lactic acid decomposed into acetaldehyde and formate, the latter being then oxidised to carbonate (Curve 12, Fig. 6).

The production of acetic acid by oxidation of the aldehyde overtook the formation of the carbonate and after about 20 minutes the curve closely resembled that plotted for the oxidation of acetic acid.

(5) Curve 6, Fig. 6, representing the oxidation of  $\beta$ -hydroxybutyric acid, showed a break similar to that obtained with lactic acid: it would be consistent with decomposition into acetaldehyde and glycollic acid, the latter being readily oxidised to carbonate and this being neutralised at first by the acid added and then by the acetic acid formed from the aldehyde.

(6) If the sodium acetoacetate (Curve 7, Fig. 6) had been rapidly oxidised to acetone and  $\text{CO}_2$ , rapid formation of carbonate would have followed and as the formation of acid from acetone is slow, the curve would have dropped rapidly and then slowly risen. Actually the formation of carbonate was considerably slower than with acetic acid, the slight subsequent rise suggesting oxidation of a neutral product such as acetone and the gradual oxidation of acetic acid.

*Application of the results of oxidations in vitro to the oxidation of the acetone bodies in the organism.*

The chief facts that have been established with regard to the fate of acetoacetic and  $\beta$ -hydroxybutyric acids in the body may be summarised as follows:

(1)  $\beta$ -Hydroxybutyric acid is burnt in the body with ease and only traces of acetoacetic acid or acetone are excreted in the urine after its injection [Mackenzie, 1902; Dakin, 1910; Blum, 1910].

(2)  $d$ - $\beta$ -Hydroxybutyric acid is more readily burnt than the laevo-form, none of the former being excreted [Mackenzie, 1902; Marriott, 1914].

(3) Administration of acetoacetic acid leads to the excretion of  $l$ -hydroxybutyric acid (Marriott, Blum).

(4) Acetoacetic acid is readily reduced in liver perfusion experiments, by liver tissue and by yeast cells [Embden and Michaud, 1908; Friedmann and Maase, 1910; Dakin, 1910]; in the presence of sugar, about 80% of added potassium acetoacetate was converted into  $d$ -hydroxybutyric acid [Friedmann, 1932]. The reverse change is less readily accomplished.

The results now presented show that when sodium  $\beta$ -hydroxybutyrate is oxidised with hydrogen dioxide in the laboratory under the prescribed conditions, only a small proportion of it is oxidised to the keto-acid, the main part

being rapidly broken down to  $\text{CO}_2$  and water without passing through acetoacetic acid. Some acetic acid is formed but formic acid if produced would have been so rapidly oxidised under the conditions of the experiment that it would not have been detected in any significant quantity.

It appears therefore legitimate to conclude that the acetoacetic acid formed by the combustion of fatty acids in the body may be reduced to  $\beta$ -hydroxybutyric acid and this acid burnt without again passing through the stage of acetoacetic acid.

We know that formic and acetic acids are normal constituents of the urine [Schotten, 1882-83; Thudichum, 1856]. When doses of 20-25 g. of these acids were given by mouth, less than 20 % formic and 10 % acetic acid were excreted. Knoop and Jost [1924] found that the injection of  $\beta$ -hydroxybutyric acid was not followed by a rise of the blood lactic acid, yet after feeding with the same acid, lactic acid appeared in the urine. They considered that this elimination was to be attributed to a stimulation of the kidneys and not to a direct conversion of the hydroxy-acid into lactic acid by  $\alpha$ -oxidation. No evidence of any other intermediaries formed in the combustion of the acetone bodies has been produced, though the existence of oxygen-containing derivatives of acetic acid seems probable.

#### *Oxidation of the fatty acids in the presence of glucose.*

The antiketogenic effect of glucose in the body has led various observers to study the effect of glucose on the oxidation of the fatty acids *in vitro* and particularly on the oxidation of acetoacetic acid.

Shaffer [1921] found that when hydrogen dioxide was added to a mixture of acetoacetic acid and glucose in alkaline solution, the acetoacetic acid disappeared rapidly at room temperature, the rate of disappearance increasing with the amount of glucose present and the degree of alkalinity. No similar reaction occurred with acetone,  $\beta$ -hydroxybutyric acid or butyric acid. It was suggested that two molecules of acetoacetic acid condensed with some oxidation product of the sugar, such as glycollic aldehyde, since this, like glucose, caused increased oxidation of the acetoacetate; the condensation product would then undergo oxidation [Shaffer and Friedmann, 1924]. Witzemann [1918] studied the oxidation of butyric acid under widely varying conditions and obtained the greater proportion of acetone the more nearly neutral the reaction mixture was kept. The acetone was more readily oxidised in an alkaline medium; the addition of glucose by developing acid oxidation products, increased the acidity of the solution and therefore the yield of acetone.

If acetoacetic acid in the body were reduced to the hydroxy-acid before it was oxidised and the effect of glucose was concerned with this reduction as in the experiments with yeast carried out by Friedmann [1932], the condensation of acetoacetic acid with an oxidation product of glucose would be without significance as to the fate of acetoacetic acid in the body.

#### *Effect of the presence of fatty acids on the oxidation of glucose.*

The oxidation of glucose was studied, the concentration of dioxide being maintained at 0.19 % and the  $p_{\text{H}}$  at 6.4.

When no copper salt had been added, the addition of the fatty acid to the glucose solution greatly inhibited the oxidation of the glucose. On Fig. 7, the amounts of hydrogen dioxide added to maintain the concentration at 0.19 % during the hour for which the experiment was carried out are shown. The total amount of decomposition of the glucose was small: it was diminished by the

addition of formic, acetic and  $\beta$ -hydroxybutyric acids and almost entirely inhibited by propionic, hexanoic and butyric acids. Fig. 8 which represents the amounts of acid and alkali added to maintain a constant  $p_H$  brings out the

Fig. 7.

Fig. 8.

Figs. 7 and 8. Oxidation of fatty acids in the presence of glucose, without a catalyst. 1, Formic acid; 2, Acetic acid; 3, Propionic acid; 4, Butyric acid; 5, Hexanoic acid; 6,  $\beta$ -Hydroxybutyric acid; 15, Glucose alone.

same relationship. The presence of hexanoic, butyric and propionic acids almost entirely prevented the formation of acid products: with hydroxybutyric, acetic and formic acids the inhibition was partial. The degree of inhibition appears to be connected with the ease with which the acid undergoes oxidation, those acids which are least readily oxidised producing the strongest effect.

#### *Oxidation of glucose and fatty acids in presence of a cupric salt.*

The results of these experiments are represented in Figs. 9 and 10: the normal decomposition rate of the dioxide was greatly stimulated by the presence of glucose alone and glucose with formic acid. It was slightly inhibited by the addition to the glucose of acetic and  $\beta$ -hydroxybutyric acids, rather more when propionic and acetoacetic acids were added and very much inhibited by the presence of butyric and hexanoic acids.

In Fig. 10 the amounts of acid and alkali which were added to maintain the constant  $p_H$  are plotted. The acid products formed from glucose were first neutralised by additional alkali, and then as these were converted to carbonate, acid was added for its neutralisation. The time for the total oxidation of the glucose was slightly less than 30 minutes. Oxidation of the formate into carbonate was very rapid: this was then overtaken by the formation of acid products from the glucose, the whole action being over, as with the glucose alone, in about 30 minutes. The effects of acetic and hydroxybutyric acids were closely similar. Butyric and hexanoic acids strongly inhibited the combustion of the glucose.

The curves in Fig. 11 represent the results produced by subtracting the effect of the fatty acid alone (Fig. 4) from the effect obtained when it was added to the glucose (Fig. 10), thus the differences due to the conversion of the sodium of the original salts into carbonate are eliminated and the residual differences represent the degree of inhibition of the combustion of the sugar.

Fig. 9.

Fig. 10.

Figs. 9 and 10. Oxidation of fatty acids in the presence of glucose using a catalyst. 1, Formic acid; 2, Acetic acid; 3, Propionic acid; 4, Butyric acid; 5, Hexanoic acid; 6,  $\beta$ -Hydroxybutyric acid; 7, Acetoacetic acid; 15, Glucose alone.

Fig. 11. Oxidation of glucose in the presence of fatty acids less the effect due to the acids alone. (Curves in Fig. 10 - curves in Fig. 4.) 1, Formic acid; 2, Acetic acid; 3, Propionic acid; 4, Butyric acid; 6,  $\beta$ -Hydroxybutyric acid; 7, Acetoacetic acid; 15, Glucose alone.

The time taken to reach the base line may be taken as the measure of the inhibition. The effect of the formic acid is very slight, those of acetic and  $\beta$ -hydroxybutyric acids are somewhat less; butyric acid is a very powerful inhibitor and acetoacetic and propionic acids are intermediate. The difference between the effects produced by  $\beta$ -hydroxybutyric and acetoacetic acids is very striking (Curves 6 and 7).

These results show that under the given conditions there is no evidence that the simultaneous oxidation of glucose increased the oxidation of the fatty acids investigated, but the fatty acids acted as inhibitors of the oxidation of the glucose by the hydrogen dioxide.

#### SUMMARY.

1. Oxidation of some lower fatty acids and their derivatives was effected by means of hydrogen dioxide at a temperature of  $90^{\circ}$ , the  $p_H$  of the reaction mixture being kept approximately constant at 6.4, and the concentration of the dioxide being kept as closely as possible at 0.19%. The amount of oxidation was greatly increased by the addition of a cupric salt.

2. The substances investigated were formic, acetic, propionic, butyric,  $\beta$ -hydroxybutyric, acetoacetic, tartaric, glycollic, oxalic, lactic and pyruvic acids and acetone.

3. Under the given conditions only slow decomposition of the acetoacetic acid took place in the absence of the oxidising agent.

4.  $\beta$ -Hydroxybutyric acid was much more readily oxidised than acetoacetic acid and the main path of oxidation does not therefore pass through the keto-acid as a preliminary stage in oxidation.

5. Lactic and  $\beta$ -hydroxybutyric acids may suffer preliminary decomposition into acetaldehyde and a molecule of fatty acid.

6. The addition of the sodium salts of the fatty acids to a glucose solution inhibited to different extents the oxidation of the glucose, and the addition of the glucose did not promote the decomposition of the fatty acids.

# CCIII. THE BIOLOGICAL VALUE OF PROTEINS.

## VI. FURTHER INVESTIGATION OF THE BALANCE SHEET METHOD.

By HARRIETTE CHICK, JOHN CHARLES DUNCAN HUTCHINSON  
AND HESTER MARY JACKSON.

*From the Division of Nutrition, Lister Institute.*

*(Received May 30th, 1935.)*

### DETERMINATION OF ENDOGENOUS NITROGEN EXCRETION.

IN attempts to compare the nutritive value of different proteins by their relative power to maintain nitrogenous equilibrium, a trustworthy estimate of the daily loss of endogenous nitrogen, for the particular experimental animal employed, is a primary requirement. The usual method is to determine the nitrogen excreted in the urine and faeces, when the diet consumed is as far as possible free of nitrogen and consists only of carbohydrate and fat, with the addition of the necessary minerals and vitamins.

In the course of a long series of experiments, in which the biological value of different proteins has been studied by the "balance sheet method", the variability in the endogenous nitrogen excretion shown by the same animal at different times has been a disturbing factor, and attempts to achieve a greater degree of constancy have not been altogether successful. The method used, employing the adult male rat as experimental animal and the formula adopted for calculating the biological value of the protein under examination have been previously described [Chick and Roscoe, 1930; Boas-Fixsen, 1930; Boas-Fixsen and Jackson, 1932].

The formula used is derived from the original expression of Thomas [1909; 1910] as follows:

The relative biological value of a protein  $X$  is expressed as:

$$\begin{aligned} 100 \times \frac{\text{Body nitrogen saved}}{\text{Food nitrogen absorbed}} \\ &= 100 \times \left\{ 1 - \frac{(\text{N excreted in experiment with } X) - (\text{N excreted on N-free diet})}{\text{True nitrogen intake in experiment with } X} \right\} \\ &= 100 \times \left\{ 1 - \frac{U_x + F_x - (F_x - F_e) - (U_e + F_e)}{I_x - (F_x - F'_e)} \right\} \\ &= 100 \times \left\{ 1 - \frac{U_x - U_e}{I_x - (F_x - F'_e)} \right\} \quad \checkmark \quad \dots\dots(1) \end{aligned}$$

where  $I_x$ ,  $U_x$  and  $F_x$  are the daily N intake, urinary N excretion and faecal N excretion, respectively, in the experiment with  $X$ ,

and  $U_e$  and  $F_e$  are the daily (endogenous) N excreted in urine and faeces, respectively, as determined in experiments on a nitrogen-free diet.

$F_x - F_e$  will represent the nitrogen in the faeces derived from undigested food and  $I_x - (F_x - F_e)$  the true N intake, in the experiment with protein  $X$ .

Any irregularity in the values obtained for  $U_e$  will affect the value of the above expression (1) more seriously when  $U_x$  and  $I_x$  are relatively small, i.e. when the protein investigated is present at a low level in the diet. In our experience a greater divergence has been found in the results of experiments with diets containing 3 % protein, than when 10 % was present.

*Duration and arrangement of experiments.*

In the past the experiments have been so arranged that each observation has lasted 4 days, with daily collection of excreta and washing of the metabolism cage. When a "nitrogen-free" diet was fed, there also was a preparatory period of one day on a low nitrogen diet, followed by 2 days on a "nitrogen-free" diet; with protein-containing diets there were two preliminary days with the diet in question before analyses were made. The rats were used for experiment in alternate weeks and during the intervening "rest" weeks they received a synthetic "complete" diet (CB) which contained 18 % protein in the form of caseinogen; this was sometimes supplemented with liver or other constituents of the ordinary stock diet during the earlier part of the rest period.

One difficulty in securing satisfactory performance during the experimental periods, especially when nitrogen-free or low protein diets were fed, is the maintenance of appetite, so that the amount eaten daily may remain constant during the 4 days of the experiment at a level sufficient to supply all energy needs from the carbohydrate and fat of the diet. We have found it a good plan to limit the consumption both of the "CB" diet in the period immediately before the experiment, and of the experimental diet during the preparatory period, to the amount that will just, and only just, maintain weight, *i.e.* about 11 to 14 g. dry food daily (all diets being arranged to contain 4 Cals. per g. from the fat and carbohydrate constituents). If any surfeit is avoided in these preparatory periods, the appetite is more likely to be maintained during the 4 days of the experiment. It has also been found advantageous to place the rat in the metabolism cage during the preliminary 2-3 day period on the experimental diet, as the change of cage may also affect the appetite. Since these precautions have been adopted, satisfactory experiments have been found easier to achieve.

The "nitrogen-free" diet used in these experiments was constituted as follows: corn starch 735, clarified beef dripping 130, salts (McCullum mixture No. 185) 50, cod-liver oil 20, and  $\text{CaCO}_3$  8. Its nitrogen content varied from 0.02 to 0.04 %. Each rat in addition received concentrates from yeast extract containing the B vitamins, the nitrogen in these amounting to 2.4 mg. per rat per day. Thus the total daily intake of nitrogen from these sources for a rat eating 12-16 g. "nitrogen-free" diet was 6-7 mg.

*Endogenous urinary nitrogen.*

There appeared to be some doubt whether the 2-3 day preparatory period was long enough to eliminate the effects of the preceding diet, especially when the change was made from a high protein to a "nitrogen-free" diet, as in experiments made to determine the endogenous nitrogen excretion. Ashworth and Brody [1933] found that the urinary nitrogen per kg. body weight excreted by rats living on a nitrogen-free diet did not reach a minimum value until 10-15 days after the beginning of the diet and that thereafter the daily variations were large. Roche [1933] obtained similar results; in some cases the endogenous urinary nitrogen per unit body weight fell continuously until a sudden rise occurred, immediately preceding the death of the animal from nitrogen starvation. Mitchell *et al.* [1922] found a rapid fall in endogenous urinary nitrogen during the first day on a "nitrogen-free" diet and thereafter a rough constancy with 2 out of 4 rats, but a slow decrease with the other two.

In order to ascertain whether in our experiments the urinary nitrogen output did further decrease after the preliminary period, a series of experiments was performed in which collections of excreta and analyses were made during

\* On low nitrogen diet, see p. 1703.

successive periods of 4 and 3 days after the preliminary period had elapsed. The results are collected in Table I and, in 9 cases out of 12, show a significant lowering of the urinary nitrogen excretion during the second period. The results of two of these experiments, with rats 72 and 78, are illustrated graphically in Fig. 1. These two observations show great similarity in the amount and constancy of the daily food intake, in the rate of fall in urinary nitrogen and in body weight over the two periods investigated and in the constancy of the amount of the faecal nitrogen.

In a further series of tests the daily collections of excreta were analysed separately over periods the duration of which was extended to 7 or 12 days. The results of five such observations on a nitrogen-free diet are given in Table II. In these experiments the daily food intake was maintained fairly constant throughout the observations. It will be seen that the rapid fall in urinary nitrogen which took place during the first 2-3 days (corresponding to the preparatory period of the ordinary test) was afterwards checked; the fall was then continued more slowly in 2 cases (rats 62 and 66), whilst a rough constancy was achieved in 3 cases (rats 64, 91 and 93). The daily variations were large, as was also found by Ashworth and Brody, and, in some cases, this probably masked the gradual fall in urinary nitrogen excretion usually shown in the longer experiments. On the whole the results of the experiments set out in Tables I and II support the view held by Ashworth and Brody [1933] and others, that the excretion of endogenous nitrogen in the urine does tend to diminish with the length of time that the rat is fed on a diet devoid of nitrogen. They also show that the preliminary period of 2-3 days, which elapsed before the experiment proper was made, was long enough to include the initial rapid fall in nitrogen excretion.

A further series of similar experiments was made with diets containing various percentages of protein, to determine whether a gradual decrease in urinary nitrogen excretion also occurred when protein was present in the diet. Table III shows the results of experiments with diets containing 5 and 7 %

Table III.

Average daily excretion of N of rats maintained on a protein-containing diet for 9-10 days, no analyses being made during first 2 days (usual preparatory period).

Protein in diet	Rat	Date	Average daily N excretion (mg. N)					
			Days 3-6		Days 7-9		Days 7-10

caseinogen and lactalbumin, respectively, which were continued for 7-8 days after the preliminary period. The excreta collected during the two divisions of the experimental period were analysed separately though this decrease was sometimes only small. In all cases there was a lowered excretion of urinary nitrogen during the second period, though the decrease was sometimes only small. A few experiments were performed with diets containing 3 and 10 % caseinogen, in which daily analyses of excreta were made for 4 days only, following the preliminary period of 2 days (see Table IV). They show that the 2-day period was long enough to include the first rapid fall in urinary nitrogen,

Table IV.

Daily excretion of nitrogen in urine of rats receiving diets containing 3 and 10 % caseinogen.

but thereafter the daily fluctuations were rather great and the experiments were of too short a duration to show whether the urinary nitrogen might not have continued to fall, if they had been continued longer. The results given in Table III with the 5 and 7 % protein diets do suggest, however, that with low proportions of protein in the diet there is a continued gradual drop in the urinary nitrogen excretion, similar to that observed with a nitrogen-free diet. This may be due to a lag in attaining equilibrium or to a diminution in the rate of nitrogenous metabolism induced by the experimental conditions. At any rate, since this drop occurs on both the nitrogen-free and low protein diets, it cannot greatly affect the calculation of the "biological value".

The estimated endogenous urinary nitrogen (as required for the calculation of biological value of proteins by the balance sheet method) must be regarded as a somewhat arbitrary quantity. It seems fair to conclude, however, that the data obtained from the analysis of the excreta collected during 4 days, after a preliminary period of 2-3 days, does give a fairly good estimate of the endogenous urinary N output when a nitrogen-free diet is fed, and of the total urinary N output when a low protein diet is fed.

#### *Endogenous faecal excretion. Relation to food intake.*

In the observations set out in Tables I and II the relative constancy shown in the endogenous faecal N excretion during the experimental periods is in contrast to the gradual fall in that excreted in the urine.

Mitchell [1924] found that for any given animal the amount of endogenous faecal nitrogen was proportional to the food intake. This relation did not appear to hold in the observations of Boas-Fixsen and Jackson [1932]. Schneider's [1934] explanation of this discrepancy points to a difference in size of the animals employed in the two investigations; young growing rats were used by Mitchell and large adult rats by Boas-Fixsen and Jackson. Schneider considers that the faecal endogenous nitrogen consists of two parts, the first being related to the food intake and the nitrogen lost in the intestinal secretions concerned in the digestive processes, and the second related to the body weight, representing an expenditure connected with the general metabolism. In small rats the amount of the first would be much greater than that of the second and there would be an apparently simple relation between the food intake and faecal nitrogen of endogenous origin.

The results of 78 experiments made recently with 21 rats of weights ranging from 250 to 500 g., fed on a "nitrogen-free" diet, are plotted in Fig. 2, and show

only a rough relationship between food intake and faecal nitrogen. The line drawn through the points is in about the same relative position as that drawn by Schneider [1934, Fig. 1]. According to Schneider's reasoning, the points corresponding to experiments made with lighter rats should show a grouping

Fig. 2. Relation between faecal nitrogen and food intake of rats receiving a "N-free" diet. +, rats weighing <350 g.; x, rats weighing 350-405 g.; •, rats weighing 405-450 g.; O, rats weighing >450 g.

below the line, while the results of those with heavier rats should tend to lie above it. Of 39 experiments with rats of body weight 250-405 g., 15 gave points above and 24 points below the line; of 39 experiments with rats of weights 405-500 g., 22 gave points above and 17 points below the line. These differences, though pointing in the direction of Schneider's reasoning, must be considered too small to be significant. It would seem that the differences in weight among our rats were not great enough to demonstrate any variations that might occur in the distribution of endogenous faecal excretion between the two constituents postulated by Schneider. When, however, the same results are plotted with the faecal nitrogen per g. food ingested against the food intake, as in Fig. 3, the shape of the curve closely resembles that given by Schneider [1934, Fig. 2], and suggests a rough general proportionality between faecal nitrogen and food intake even for rats of 250-500 g. weight, provided the food intake is greater than 9-10 g. daily (approx. 100-120 Cal./kg. body weight). In our experiments, therefore, the direct proportion between food intake and faecal nitrogen is only very approximate (see Fig. 2). Seeing that in any case the amount of the faecal endogenous nitrogen has relatively little influence on the value of the expression used for calculating the biological value (see p. 1702), we have taken the mean value of the actual faecal nitrogen excreted in all the nitrogen-free experiments

performed on any rat, as a reasonably good estimate of the endogenous faecal nitrogen for that rat, following the previous usage in this laboratory.

Schneider [1934] considers that estimations of endogenous faecal nitrogen should be made with nitrogen-free diets containing the same amount of roughage

Fig. 3. Relation between daily food intake and faecal nitrogen per g. dry food eaten for rats receiving a "N-free" diet.

as the protein-containing diet under examination, since this secures more regular elimination of faeces and more comparable amounts of food to be digested. We have made a number of comparable observations with nitrogen-free diets and those containing caseinogen as protein, in which filter-paper was present in the proportion of 4 % of the food, but in these experiments the effect of the paper appeared to be unimportant.

#### *Urinary endogenous nitrogen in relation to food intake and body weight.*

Mitchell [1924] found the urinary endogenous nitrogen excreted by rats to be proportional to the body weight. In our experiments, we have found no greater constancy in the ratio  $U_e$  per kg. body weight than in the value  $U_e$  itself, which, for the adult male rats used, was usually between 80 and 100 mg. per day. This constancy may be due to the fact that our rats were all large and adult and that the difference in body weight (250–500 g.) largely consisted in differences in body fat. There was, however, a tendency for the urinary excretion to be high when the loss in body weight during an experiment was great, corresponding to a low intake of the "N-free" diet. When the results of 65 experiments on 21 rats are considered together, the mean urinary nitrogen for the

20 experiments in which the daily intake of dry food was less than 10 g. (approximately 100–120 Cal./kg.), was found to be greater (average 96.5 mg. daily) than for the 45 experiments in which more than this amount was eaten (average 80.2 mg.). This difference, on analysis, was found to be statistically significant. If, however, the results of experiments in which less than 6 g. of the "N-free" diet were consumed daily are omitted, the difference of these averages was no longer found to be significant (average daily urinary excretion, 89.5 mg. for intake of 6–10 g., and 80.2 mg. for intake of over 10 g.). In any case, the experiments in which less than 10 g. daily of dry food were eaten formed only a small proportion of the total number of "N-free" experiments. It was thought wise, therefore, in our estimate of the endogenous nitrogen excretion for use in the calculation of the biological value of proteins (see the following paper), to exclude only the results of "N-free" experiments in which less than 6 g. dry food were eaten and the urinary N output was abnormally high. With this exception in our calculation of biological values, we have continued to use, as estimate of the endogenous urinary nitrogen excretion, the average of all values obtained with the rat in question, during a 3-month period before, and a 3-month period after, the date of the experiment with the protein under investigation.

The results and conclusions set forth in this paper are in accord with some published quite recently by Mason and Palmer [1935] in an investigation of the biological value of gelatin, caseinogen and zein. In special experiments made to determine the length of time on a N-free diet required to bring the urinary nitrogen to the endogenous level, only a very slight decrease was found after the third day; a 3-day preparatory period was therefore adopted. The authors also found that a "fall in calorie intake somewhat below the theoretical requirements during the 'nitrogen-free' feeding period was of no apparent significance" and that, with large adult male rats, loss of weight during a short experiment was without effect on the urinary nitrogen excretion.

#### SUMMARY.

1. Adult rats, when transferred from a high protein (18 %), to a "nitrogen-free", diet and maintained thus for periods extending to 10–14 days showed a rapid fall in urinary nitrogen during the first 2–3 days, followed by a very gradual decrease subsequently. Similar changes in urinary nitrogen excretion were observed when the change was made from a high to a low protein diet.
2. The faecal endogenous nitrogen excretion showed a greater degree of constancy in experiments of similar duration and the amount was roughly proportional to the food intake when this was equivalent to not less than 100–120 Cal./kg.
3. The "balance sheet" method, as used in this laboratory, in which the endogenous nitrogen output on a nitrogen-free diet and the nitrogen intake and total output on the protein-containing diet are estimated during a 4-day period following a preparatory 2–3 days on the diet in question, is considered to afford reasonably satisfactory estimates of these values for use in the calculation of the biological value of the protein investigated.

We desire to express our thanks to the Medical Research Council for a personal grant to one of us (J. C. D. H.) and to Miss Phyllis Ponsford for assistance in some of the analytical work and calculations. We are also indebted to Mr Walter Acton of Messrs MacKean, Paisley, for supplying us with a highly purified specimen of corn starch for incorporation in our "nitrogen-free" diets and low protein diets.

## CCIV. THE BIOLOGICAL VALUE OF PROTEINS.

### VII. THE INFLUENCE OF VARIATION IN THE LEVEL OF PROTEIN IN THE DIET AND OF HEATING THE PROTEIN ON ITS BIOLOGICAL VALUE.

BY HARRIETTE CHICK, MARGARET AVERIL BOAS-FIXSEN,  
JOHN CHARLES DUNCAN HUTCHINSON  
AND HESTER MARY JACKSON.

*From the Division of Nutrition, Lister Institute.*

*(Received May 30th, 1935.)*

MITCHELL [1924, 2], using young growing rats as experimental animals, found that the biological value of proteins was lessened as the proportion of the protein in the diet was increased. He considered that this result might in part be due to the fact that proteins could be used more economically for maintenance than for growth. When supplied in the diet in a low proportion, almost all the protein would be used for maintenance, whilst, as the level was increased, an increasing proportion would be used for growth. Martin and Robison [1922], working on themselves, found that the value of wheat proteins for the maintenance of nitrogenous equilibrium remained steady when these were present in the diet at different levels; the values they obtained for milk proteins, on the other hand, were most irregular. Boas-Fixsen and Jackson [1932], using adult male rats as experimental animals, found that the biological value of maize protein was increased when its level in the diet was lowered, but Boas-Fixsen [1930] found no progressive change in the nutritive value of a sample of dry-heated, purified caseinogen when the amount present in the diet was raised from 5 to 15 %, the values obtained being uniformly low.

The experiments to be described were designed to find out whether the biological value of proteins for maintenance was increased at very low levels in the diet for all proteins, or whether this effect was peculiar to a few. Experiments were therefore planned using diets containing only a low proportion (3-4 %) of the proteins used by Boas-Fixsen and Jackson [1932], *viz.* wheat, white flour, wheat germ, maize endosperm, milk and lactalbumin, for comparison with the results of their previous experiments with diets containing 5-7 % of these proteins. A series of experiments was also performed with caseinogen in various forms, *i.e.* "light white" (commercial), heated, heated and purified, and roasted, to determine the effect of heat and purification on its biological value as well as that of variation in the proportion contained in the diet. The levels of the caseinogen in these diets varied from 3 to 10 %. The effect of heat on lactalbumin was also investigated.

#### EXPERIMENTAL.

##### *Materials used.*

The samples of whole wheat, white flour, wheat germ, maize endosperm and whole milk were the same as those used in the previous investigation [Boas-Fixsen and Jackson, 1932]. The various types of caseinogen used were the following:

(1) "Light white casein" (B.D.H.), a commercial sodium caseinogenate prepared by Hammarsten's method.

used for vitamin work, if the temperature at which it is heated does not exceed about 125°. It should be remembered, however, that the above results refer to maintenance tests on adult rats, whereas in vitamin work, young growing rats are usually employed. The usual proportion of caseinogen in these basal diets, on the other hand, is relatively very high (18–20 %).

Table III. *Effect of heat on the percentage digestibility of caseinogen (5 % protein in the diets).*

Rat No.	Unheated caseinogen	"Heated" caseinogen (approx. 120° for 72 hrs.)	"Roasted" caseinogen (approx. 150° for 66 hrs.)
59	—	95	—
63	—	92	—
66	—	95	—
72	90	{ 95 100	—
73	—	98	—
74	92	—	63
77	96	97	84
78	94	—	69
79	—	92	76
87	92	94	—
Average	93	95	73

Table III shows the percentage digestibilities of the raw, "heated" and "roasted" caseinogen, as calculated from the results of experiments with 5 % protein in the diet. They show that prolonged heating at about 120° did not affect the digestibility, but that stronger heating at approximately 150° reduced it from 93 to 73 %.

(b) *Lactalbumin*. To investigate the effect of heat (112–125°) on the nutritive value of lactalbumin, diets containing 5 % lactalbumin and 7 % heated lactalbumin were used (see Table IV). The heating decreased the digestibility of the lactalbumin from 95 to 69 % (average values). Hence the content in each of the two diets was equivalent to about 5 % digestible protein. The heating decreased the biological value by about one-fifth (B.V. = 66 for the unheated, and 56 for the heated, specimen).

Table IV. *Effect of heat on the biological value and on the digestibility of lactalbumin (72 hours at approximately 120°).*

Rat No.	Biological value*		% digestibility	
	Unheated	Heated	Unheated	Heated
75	64	59	98	75
76	65	52	92	67
79	72	58	96	73
87	64	47	93	61
89	64	65	94	69
Means	66	56	95	69

\* Both diets contained 5 % digestible protein.

Heating the lactalbumin appeared to cause some physical change, so that it could not be so well digested, whilst the biological value of the absorbed portion was also reduced, but to a less degree. It should, however, be noted that these experiments were concerned with the value of the lactalbumin for maintenance, and the effect of this degree of heating might have been much more serious on its value for supporting growth.

*The balance sheet method.*

The balance sheet method, by which the nutritive values of different proteins are compared in regard to their relative values for maintenance of nitrogenous equilibrium in the adult animal, has many drawbacks. The method is difficult and laborious in practice and the results are subject to a margin of error which is large even for biological experiments. Long experience and skill in management of the experimental animals are needed in order to achieve a series of comparative observations, possessing even the somewhat low degree of accuracy of the work reported in this paper and the preceding ones of this series. There is also a limit to the duration of the experiment, which militates against accuracy. This is specially true for the observations on "N-free" diet, made to determine the endogenous nitrogen expenditure, which form an essential part of the method. Even in the experiments in which protein is fed, the nitrogen balance should be negative and animals cannot be maintained in health for more than short periods in negative nitrogen balance. It is also possible that a large nitrogen debt may affect the biological value of a protein for maintenance.

Other methods of studying the value of proteins, in which the criteria adopted are the support of growth and development in young animals [Osborne *et al.*, 1919] or the complete maintenance of the species including reproduction and lactation [Osborne *et al.*, 1919; McCollum *et al.*, 1921, 1, 2, 3] are simpler in conception and appear, at first sight, to yield more useful information. In practice, however, such experiments are often very difficult to carry out in such a way that the proteins compared are observed under truly comparable conditions. The appetite and preferences of the experimental animals often present serious complications under these more "natural" conditions. For these reasons the results of the observations are often difficult of interpretation or of utilisation for conclusions having a quantitative value.

Maintenance of body weight has been used by Osborne and Mendel [1916, 2] as a criterion of the value of different proteins for maintenance, apart from growth. Their experiments were made with rats of weight from 100 to 170 g., *i.e.* rats rather less than half grown, whose bodies would contain relatively little fat. If the method were applied to adult animals, variations in the fat content of the carcass might prove a serious complication in interpreting the results.

It is not easy to appraise the relative merits of the different types of investigation. These are well discussed in Mitchell's [1924, 3] admirable review, and, more recently, by Boas-Fixsen [1935]. Biological values of proteins for maintenance as opposed to growth and other functions, are, however, of interest since their relative values for different functions are probably different, depending on their make-up of amino-acids. In the experiments of Osborne and Mendel [1916, 1, 2] lactalbumin showed a degree of superiority over caseinogen and edestin for supporting growth, which was much greater than the superiority for maintenance. This is doubtless to be explained by the large requirement for growth of lysine and the relatively small need of this amino-acid for maintenance. Conversely, the proteins of raw ox muscle were found by Morgan and Kern [1934] to be inferior to those of milk or cereals for maintenance, whilst superior for the support of growth.

In the one instance in which both the "balance sheet" and the "growth" methods were used by the present group of workers to compare the same proteins, those of wheat and maize, and the more obvious errors of the second method were satisfactorily avoided, the results obtained were concordant, *i.e.* no significant difference was detected by either method in the values of the proteins from the two sources compared [Boas-Fixsen and Jackson, 1932; Boas-Fixsen *et al.*, 1934].

## SUMMARY.

1. The biological value for the maintenance of nitrogenous equilibrium in the adult rat has been determined for proteins from the following sources, at levels in the diet varying from 3 to 10 %: whole wheat, white flour, wheat germ, maize endosperm, whole milk, lactalbumin, heated lactalbumin (at approximately 120° for 72 hours), caseinogen, heated caseinogen (at 112–125° for 72 hours), heated caseinogen purified by reprecipitation and extraction with dilute alcohol.

2. With the exception of whole milk proteins, the B.V. of which remained uniformly high at all levels, increasing the proportion of protein in the diet from 3 to 5, 7 or 10 %, lowered the biological value.

3. The biological value of caseinogen was not lowered significantly by heating the caseinogen at 112–125° for 72 hours or by further purification. Heating at about 150° for 66 hours did, however, decrease the biological value from 64 to 44 (5 % protein in the diet), and also reduced the digestibility from 93 to 73 %.

4. The biological value of lactalbumin was only slightly reduced by heating the lactalbumin at about 120° for 72 hours, but the digestibility was lowered from 95 to 69 %.

Two of the authors (M. A. B.-F. and J. C. D. H.) wish to express thanks to the Medical Research Council for personal grants and one (J. C. D. H.) for a Studentship in Animal Health of the Ministry of Agriculture, held subsequently. Our thanks are also due to Miss Phyllis Ponsford for help in some of the analytical work and calculations.

# CCV. THE ASSAY OF CRYSTALLINE MALE SEXUAL HORMONE (ANDROSTERONE).

BY VLADIMIR KORENCHEVSKY AND MARJORIE DENNISON.

*From the Lister Institute.*

*(Received May 31st, 1935.)*

RUZICKA *et al.* [1934] have prepared from *epidihydrocholesterol*, an oxyketone having the formula  $C_{19}H_{30}O_2$ , which in composition, melting point, optical activity and effect in stimulating comb-growth in capons appears to be identical with the crystalline hormone isolated from human urine by Butenandt and his co-workers [1932; 1934]. Butenandt [1934] found that one capon unit was contained in about 150–200 $\gamma$  of his preparation of androsterone, whilst Tschopp [Ruzicka *et al.*, 1934, p. 1398; 1935, p. 211], using an assay technique similar to that used by Butenandt, found the same value for Ruzicka's androsterone. Tschopp [Ruzicka *et al.*, 1934, p. 1401], using only a small number of castrated rats, has also found that the prostate, seminal vesicles and penis became enlarged after the injection of Ruzicka's androsterone.

This paper contains the results of our assay of androsterone synthesised by Ruzicka using the method and definition of the rat unit described in a previous paper [Korenchevsky and Dennison, 1934, 2, p. 1498]. The preliminary results with this material were published elsewhere [Korenchevsky, 1935].

In addition to the effects obtained on the secondary sexual organs, the changes in some of the other organs investigated are also described.

## *Technique.*

The experiments were performed on 74 castrated rats belonging to 15 litters. The technique used was described in detail in our previous papers [Korenchevsky *et al.*, 1932; 1933; 1934]. Since rats are more liable to develop pneumonia during the winter than during the summer months, for about 10 days before the experiments the doses of cod-liver oil and raw liver were greatly increased with the object of increasing their resistance to infection. The effect on the deposition of fat was very irregular, the amount of fat in different rats varying greatly. The results given by the calculation of the weight of the organs per unit of body weight were therefore a little less regular than the actual weights.

1.2 g. of androsterone were received from Prof. Ruzicka in three batches, which were carefully mixed and kept in a vacuum in the cold store. A weighed amount of androsterone was dissolved in alcohol and poured into warm olive oil. Traces of alcohol were then removed as completely as possible *in vacuo* at about 80–85°. We stress this point of complete removal of alcohol, since any alcohol left in the oily solution may alter the absorption of androsterone from the oil and may therefore change the results of assay.

The oily solution of androsterone was filled into ampoules and sterilised in the steamer for 30 minutes on 3 consecutive days. 0.2 ml. per day of oily solution of different strengths was injected subcutaneously, 0.1 ml. being injected twice a day for 7 consecutive days and the rats killed on the 8th day.

Doses of 67, 200, 450, 600, 900, 1350 and 1800 $\gamma$  per day were used. Since the effect produced by 67 $\gamma$  was so small as to be within the physiological variations and only 2 rats were injected with this dose, the effect of this dose is not included in the tables or curves.

All the rats were castrated before sexual maturity and the experiments started from 28 to 42 days after castration, the final age varying from 53 to 66 days. One or two rats in each litter were used for the control group, the remaining litter-mates being injected. The groups of injected litter-mates contained from 1 to 4 rats according to the number of rats in the litter.

In Table I are given the number of rats in the litter, the age and the average final weights of the rats in each group in each litter.

*The effect on the prostate, the seminal vesicles and the prostate and seminal vesicles weighed together.*

The results obtained are summarised in Tables II–VI and are represented graphically by the curves in Figs. 1–4. The latter give the relation between the dose of androsterone and the percentage increase obtained in the weight of the organ.

Since the seminal vesicles weigh only one-fifth or less of the weight of the prostate and since the percentage increase in weight under the influence of different doses of androsterone (Table VI) is roughly parallel with that of the prostate, the curves representing the changes in the weight of the prostate alone and of the prostate with seminal vesicles were very similar (Figs. 1–4). For economy of space we do not give the curves for the seminal vesicles since these data are unsuitable for the purpose of assay. The changes obtained in the weights of the seminal vesicles (see average figures, Table VI), besides being more irregular, do not represent such a simple proportional relationship to the dose as those of the prostate and of the prostate weighed with the seminal vesicles.

Table II. *Influence on prostate.*

The actual average weights of the prostate of rats in each group of each litter and the percentage increase after the injection of androsterone.

From the comparison of Fig. 1 with Fig. 2 and of Fig. 3 with Fig. 4 it is clear that the changes calculated from the actual weights of the organs and from those per 200 g. of body weight are similar.

We also found this to be so in our previous investigation on the effect of a testicular hormone preparation extracted from human urine [Korenchevsky *et al.*, 1932; 1933, 1, 2]. However, from the comparison of the data given in the papers just cited with those in Tables IV and V it follows that the variation in the percentage increase obtained in different litters with the same dose was less with urine preparations than that observed in the present experiments with androsterone.

In spite of this difference between the individual litters, in both cases (with testicular hormones extracted from human urine and with androsterone) the relation between the dose and the average percentage increase in the weight of the prostate or prostate with seminal vesicles appeared to be directly proportional, within a certain range of the doses. In the case of androsterone this part of the curve lies between the doses 200 and 900 $\gamma$  and can for practical purposes be represented by a straight line (the continuous line in Figs. 1-4). When the

whole range of the doses of androsterone used was included in the curve, a cubic curve was found to fit the results most closely (dotted lines in Figs. 1-4). As can be seen from the curves, there is little difference between the cubic curve and a straight line with doses of 200-900 $\gamma$ .

The next doses used (1350 and 1800 $\gamma$ ) lie on a flattened portion of the curve. As we used fewer litters for this part of the curve (as not being suitable for assay), too much reliability must not be attached to the slight dip in the end of the curve, which is shown by the highest dose used (1800 $\gamma$ ).

*The relation between the rat unit and androsterone activity.*

The data referring to the average activity of androsterone and the rat unit are summarised in Table VII. In column I is given the amount of the dose injected in  $\gamma$ . In column II is given the average percentage increase in weight of the organs per 100 $\gamma$  for doses from 200 to 900 $\gamma$ . The values for the prostate are very close to those for the prostate with seminal vesicles, both the actual figures

(24.7 and 24.3 % respectively) and those calculated per unit of body weight (23.7 and 23.3 % respectively). There is also little difference between the percentage increase calculated from the actual figures and from the figures per unit of body weight in the case of these two organs, e.g. 100 $\gamma$  gave 24.7 % increase in the actual weight of the prostate and 23.7 % increase when calculated per 200 g. of body weight. From Table VI it can be seen that the respective data

(last column) for the seminal vesicles were 23.0 and 22.6 %, *i.e.* results very close to those for the prostate.

The values of column III are obtained from those of column II and our definition of one rat unit of testicular hormone [Korenchevsky and Dennison, 1934, 2, p. 1498] as that amount which produces 40 % increase in the weight of the prostate alone (for "comb growth" activity) or in the weight of the prostate with seminal vesicles (for "whole male sexual" activity). Again, as in column II, the values in column III are very close, one rat unit of "comb growth" activity being contained in 162–169 $\gamma$  and of "whole male sexual" activity in 165–172 $\gamma$ .

In the preliminary communication [Korenchevsky, 1935] an approximate estimation was based on experiments with only a few rats and these values were given as 175 and 179 $\gamma$ , which are very close to those now given, being obtained from a sufficiently large number of rats to yield reliable figures.

In columns IV and V of Table VII percentage increases actually obtained are compared with those which would be theoretically expected assuming the average value given in column II and a direct proportional relationship between the dose and percentage increase. This comparison shows that the figures actually obtained were very close to these theoretical figures for doses 200–900 $\gamma$  and that the divergence increases considerably with higher doses.

Column VI gives the amount of androsterone injected as expressed in rat units and shows that the direct proportional relationship between the dose and the effect existed, approximately, from 1 to 6 rat units and that a definite flattening of the curve was observed when 8 or more rat units were injected.

*A statistical interpretation of the results obtained in the assay.*

With the kind permission of Dr E. S. Pearson we include his opinion as expressed in the following quotation from his letter.

"Let us denote by  $y$  the percentage increase in an organ obtained on applying Dr Korenchevsky's procedure to a litter of rats, one group of the litter being treated as a control and the remainder injected with a dose of  $x\gamma$ . For example, from Table II it is seen that for litter No. 8,  $y = 192$  %, for  $x = 900\gamma$ . Then the four diagrams show as black spots the average values of  $y$  plotted against  $x$ . Cubic curves, constrained to pass through the origin, have been fitted to these averages, using the method of least squares and giving all averages equal weight. These curves are useful for graduation purposes, but no great stress should be laid on their precise form, particularly in the region of large doses.

For the range of doses 200–900 $\gamma$ , it is clear that a good approximation to the assay curve will be obtained by a straight line. The slopes of these lines and their probable errors have been calculated as follows. An examination of Dr Korenchevsky's results shows that, whilst the variation in  $y$  from litter to litter increased steadily with  $x$ , the variation in the ratio

$$\frac{y}{x} = \frac{\% \text{ increase in organ} \times 1000}{\text{dose}} = z, \text{ say,}$$

remains approximately constant. A useful measure of the reliability of an assay appears, therefore, to be the probable error of  $z^1$ .

<sup>1</sup> In making these calculations it has been tacitly assumed that all the experimental results might be regarded as of equal value, irrespective of the number of rats in the litter. From the statistical point of view this is not completely satisfactory, but if further assays are made with at least 2 control rats and 2 dosed rats per litter, the probable error to be expected will be less than that allowed for in the following discussion.

The following Table VIII shows:

Column 1. Organ and basis of calculation.

Column 2. Average value of  $z$  for the 22 groups injected (doses 200, 450, 600 and 900 $\gamma$  only being considered). This represents in the range 200–900 $\gamma$ , the average percentage increase in organ per 1000 $\gamma$  of the drug, and determines the slope of the straight lines shown in the diagrams.

Column 3. Probable error of Dr Korenchevsky's averages given in column 2. These probable errors are  $1/\sqrt{22}$  times those given in column 4 (the figure being raised to the next highest integer when a decimal place occurs).

Column 4. Probable error of a value of  $z$  determined from a single litter.

Column 5. Probable error of  $z$  determined from the average of 3 litters. These figures are  $1/\sqrt{3}$  times those given in column 4.

Table VIII. *Statistical summary of results of experiments*  
(E. S. Pearson).

(1)		(2)	(3)	(4) Probable error of $z$ if determined		(5)
Organ and basis of calculation		Average $z$ (22 groups of rats)	Probable error of average $z$ (22 groups)	From a single litter		From three litters
Prostate	{ Actual weight	245	$\pm 8$ (3 %)*	$\pm 34$ (14 %)*		$\pm 20$ (8 %)*
	{ per 200 g.	233	$\pm 10$ (4 %)	$\pm 43$ (19 %)		$\pm 25$ (11 %)
Seminal vesicles	{ Actual weight	230	$\pm 13$ (6 %)	$\pm 57$ (25 %)		$\pm 33$ (15 %)
	{ per 200 g.	223	$\pm 15$ (7 %)	$\pm 69$ (31 %)		$\pm 40$ (18 %)
Prostate and seminal vesicles	{ Actual weight	241	$\pm 6$ (3 %)	$\pm 24$ (10 %)		$\pm 14$ (6 %)
	{ per 200 g.	228	$\pm 9$ (4 %)	$\pm 38$ (17 %)		$\pm 22$ (10 %)

\* The figures in brackets are the values of the probable errors expressed as a percentage of the average  $z$  of column (2).

The figures given in brackets in columns (3), (4) and (5) are the values of the probable errors expressed as a percentage of the average figure given in column (2), e.g. row 1, column 4 gives 34 (14 %), since 34 is 14 % of 245.

The results shown in the table suggest that in the present case somewhat more reliable assays can be made using the actual weights of organs rather than by adjusting these to body weight. They also show that the seminal vesicles alone give more variable results than those for the prostate.

Should an experimenter in further work wish to judge whether the difference between his assay and Dr Korenchevsky's is significant, this may be done as follows: suppose after treating 4 litters with a dose of androsterone, containing, he believes,  $x=600\gamma$ , he finds an average increase in prostate (based on actual weights) of  $y=126\%$ ; this corresponds to a value of  $z = \frac{126 \times 1000}{600} = 210$ ; on the assumption that his technique is as reliable as Dr Korenchevsky's, the probable error of this  $z$  based on 4 litters will be  $\frac{34}{\sqrt{4}} = 17$  (using the appropriate probable error from row 1, column 4 of the table). Thus he must compare  $210 \pm 17$  with Dr Korenchevsky's  $245 \pm 8$ . The difference is 35 and its probable error

$$\sqrt{(17)^2 + (8)^2} = 19,$$

that is to say, the difference is barely twice the probable error and cannot be regarded as significant."

*The effect of androsterone on the weight of the penis and preputial glands.*

The average data for these glands are summarised in Table VI. They show an increase in the effect on the glands with an increase in the dose, the effect, however, being much less regular than in the case of the prostate. The flattening of the curve was also noticeable with higher doses.

If we assume the values given in column 3, Table VII of 165 $\gamma$  (actual figures) and 172 $\gamma$  (per unit of body weight) for one rat unit of "whole male sexual" activity, the increase in the weight of the penis per rat unit of androsterone will be 18.2 and 17.17 % respectively. A comparison of these figures obtained by androsterone injections with those previously obtained by injections of testicular hormone preparations extracted from human urine [Korenchevsky *et al.*, 1932, pp. 2100-2101], shows a very close similarity in the results which in these earlier experiments were 18 % (actual figures) and 15 % (per unit of body weight) increase in the weight of the penis per rat unit. The response of the preputial glands to the injections is greater than that of the penis (Table VI), 100 $\gamma$  producing an increase of about 18 % or 30 % per rat unit.

*Effect on the other organs investigated.*

In addition to the effect on the sexual organs an investigation was made of the changes in weight of the thymus, adrenals, thyroid and intra-abdominal fat.

The only changes observed were a decrease in most cases in the weight of the thymus and the adrenal glands of 10-30 % both in actual figures and those per unit of body weight.

## DISCUSSION.

A saturated solution of androsterone in olive oil contains about 1 % of androsterone when, as far as possible, all traces of alcohol, the intermediate solvent, are removed from the oil *in vacuo*; *i.e.* androsterone is not very soluble in oil. The results of our assay, therefore, apply only to the oily solution of the hormone free from alcohol, since it is probable that the use of other solvents or the non-removal of all or part of the intermediate solvent would result in a different rate or degree of absorption of the hormone from the subcutaneous tissue, giving an apparently different activity for the preparation. We injected all doses as the same quantity (0.2 ml. per day) of solutions of different concentrations. It is possible that different results would be obtained by using varying quantities of a solution of one concentration only. These points are a matter for further investigation.

By our method, the part of the curve corresponding to doses of 200-900 $\gamma$  was found to be suitable for the assay of the "comb growth" activity and the "whole male sexual" activity of androsterone ("assayable part of curve"). As we had found in our previous experiments with the testicular hormone preparations extracted from human urine, the rat units of these two forms of activity proved to be nearly identical, owing to the fact that both these hormones had about the same quantitative effect on the prostate alone as they had on the seminal vesicles alone.

In addition to this similarity it was found that on the average the effects on the penis of the natural preparations used and of the artificial hormone were also nearly the same.

The direct proportional relationship between the dose and the effect, within certain limits of the dose, and the approximate equality of the rat and capon units were also points of similarity between the natural and artificial preparations.

One difference must be considered here, the flattening of the curve with the

higher doses of androsterone, which we were unable to obtain with 8 c.u. of the "natural" hormone preparation. This is perhaps related to different rates of absorption from nearly saturated solutions. Our present results, however, cannot be compared with any of the "natural" preparations we received from various firms, since:

- (1) intermediate solvents may not have been completely removed;
- (2) the preparations may have contained other testicular hormones capable of increasing the effect of androsterone.

We have suggested several times in our previous papers that there is probably more than one testicular hormone present in the organism.

As an *international unit of androsterone* in pure oily solution that dose is preferable which will give the smallest definite physiological effect. We have found for the prostate and prostate with seminal vesicles this dose to be that which produces 40 % increase in the weight, actual or per unit of body weight. Therefore, from our results, taking into account that the probable error of our present results does not seem to be more than  $\pm 5\%$ , 170 $\gamma$  of androsterone might be suggested as one rat unit, or alternatively, since one capon unit has been found to vary from 150 to 200 $\gamma$  of androsterone, either of these round figures might be more suitable, being applicable to both methods. In our previous papers we suggested that the assay should be made with at least 3 litters, provided that there are at least 2 rats in each group. The present experiments show (Table VIII, column 5), that with 3 litters the probable error would be less than  $\pm 12\%$ , which for practical purposes, is quite satisfactory.

Up to the present, we have published all our results expressed both as actual weights and the weights per unit of body weight, since they serve as a check, the one to the other and there are arguments for and against both methods of calculation. We ourselves feel confident in the reliability of the results only when the general averages expressed as percentage changes by the two methods are as close as they are for instance in the present or our previous papers.

Dr Pearson finds that the actual results are less variable than those calculated per unit of body weight. That this could be so, can best be explained by the following example of groups I (litter-mates of similar weight) and II (litter-mates of dissimilar weight) (see Table below) taken from the present experiments of the assay of androsterone.

No. of group	No. of litter-mate	Body weight	Weight fat (g.)		Weight of prostate (mg.)	
			actual	per 200 g.	actual	per 200 g.
I	{ 1	237	6.6	5.6	211	178
	{ 2	215	6.8	6.3	176	164
II	{ 3	232	9.7	8.4	195	168
	{ 4	170	3.0	3.5	219	258

If the deposition of fat in the rats does not differ greatly, the two values, actual and per 200 g. of body weight, are very close and the weights of the sexual organs seem to be approximately proportional to the body weight (see group I). If the deposition of fat in the rats is very different, so that the weight of the rat is considerably influenced by it, the weights of the sexual organs may be close in actual figures and become, it seems fallaciously, very different per unit of body weight (see group II). Probably physiological variations in the size of the rats are of different origin from those produced by pathological factors, which factors however are often not detectable at autopsy. Consequently the exclusion of a suspicious (because irregular) rat from the results is not justified.

## SUMMARY.

1. Pure crystalline testicular hormone, prepared by Ruzicka, was dissolved in olive oil and assayed by the author's method on 74 castrated male rats.

2. A relation was found to exist between the dose and the effect of androsterone on the secondary sexual organs, this relation being investigated statistically and represented graphically in the case of the prostate and the prostate with seminal vesicles.

3. The "assayable" part of the curve for these organs for the purposes of assay may be represented between the doses 200 and 900 $\gamma$  ("assayable" doses) by a straight line.

4. One rat unit of both "comb growth" activity and "whole male sexual" activity was found on the average to be contained in approximately 170 $\gamma$ , which is also approximately the same amount as that found by other workers for the capon unit.

5. This figure, or the round number 150 or 200 $\gamma$ , is suggested as one international unit of androsterone, being suitable both for the assay by the capon method and by our rat method.

6. The probable error of our value of the rat unit of androsterone is less than  $\pm 5\%$ , if all 11 litters injected with assayable doses are taken into consideration.

7. The points of similarity and dissimilarity between androsterone and the purified preparations of the hormone extracted from human urine have been discussed.

8. In making an assay, the results obtained from the actual weights should be checked by those calculated per unit of body weight and the two results should be in close agreement, when expressed as the percentage changes in the weights of the organs.

Grants from the Medical Research Council and from the Lister Institute have enabled us to carry out this work and to them our thanks are due. We are much indebted to Dr E. S. Pearson and to the Department of Applied Statistics of University College for so kindly helping us in the statistical interpretation of the results obtained.

# CCVI. THE IDENTITY OF XANTHINE OXIDASE AND THE SCHARDINGER ENZYME.

BY VERNON HOLLIS BOOTH.

*From the Biochemical Laboratory, Cambridge.*

*(Received May 30th, 1935.)*

## THE ORIGIN OF THE PROBLEM.

SCHARDINGER [1902] observed that methylene blue was reduced by formaldehyde in the presence of fresh milk. The enzyme concerned in the oxidation of this and other aldehydes became known as "Schardinger's enzyme".

Hopkins [1921] found that certain extracts of yeast and of animal tissues also reduced methylene blue when added to milk. Morgan *et al.* [1922] identified the reducing substance as hypoxanthine and showed that its oxidation was effected by a system similar to that present in tissues. These authors first established that "xanthine oxidase" had many properties in common with the Schardinger enzyme. They found that tissues which were capable of oxidising purines would in all cases also oxidise aldehyde. This striking parallel occurrence of xanthine oxidase and the Schardinger enzyme in milk and in tissues raised the question of their identity. These authors concluded that identity was improbable, because (a) the extreme specificity of enzymes towards their substrates argues in general against one and the same enzyme activating substances so different as purines and aldehydes; (b) the optimum concentration of purine was only one-hundredth of the optimum concentration of aldehyde; (c) the relative activities of the two enzymes varied from one sample of milk to another.

Dixon and Thurlow made a preparation of xanthine oxidase from milk [1924, 1] and studied the dynamics of the enzyme system [1924, 2]. They discussed the following evidence for and against its identity with the Schardinger enzyme. (a) Uric acid inhibits both enzymes to a marked extent. The inhibition of an aldehyde oxidase by a purine speaks for identity. (b) The slight inhibition by fluoride and cyanide is identical for each enzyme. (c) The enzymes cannot be separated: whenever one is precipitated, adsorbed, extracted or destroyed so also is the other. (d) The  $p_{\text{H}}$ -activity curves with purines and with aldehyde each show a sharp break at  $p_{\text{H}}$  9 which in all cases is due to destruction of enzyme. (e) There is a striking parallelism between the activities of the two enzymes in a large number of defatted preparations. The variations in relative activities observed by Morgan *et al.* were never great and could be explained by variations in the fat content of different samples of milk. (Dixon and Thurlow observed that fat accelerated the oxidation of hypoxanthine but not of aldehyde.) (f) The disparity in optimum concentrations of the two classes of substrate cannot be used as an argument against identity since several cases are known of one enzyme activating two substrates at very different optimum concentrations. These authors concluded that the balance of evidence was in favour of identity though it was not sufficient to justify a positive statement to that effect.

Morgan [1926] studied the distribution of xanthine oxidase in tissues from many animal species. Wherever xanthine oxidase was found it was invariably

accompanied by the Schardinger enzyme<sup>1</sup> and this concomitance was offered as evidence for identity.

Sbarsky and Michlin [1926] made a purified preparation of the Schardinger enzyme and found that it also had xanthine oxidase activity.

More recently Wieland and co-workers have claimed to have demonstrated the non-identity of these enzymes. Wieland and Rosenfeld [1930] observed a change in the ratio of the activities of the two enzymes after treating the milk preparation with adsorbing agents. This was taken to mean that partial separation had been achieved. Shortly afterwards Wieland and Macrae [1930] found that the velocity of reduction of methylene blue with xanthine and aldehyde both present together was greater than with either alone (method of summation or addition).

On the other hand Sen [1931] found that the oxygen uptake rates with hypoxanthine and aldehyde were not additive. He submitted this effect as evidence for the identity of the enzymes.

In view of Sen's results Wieland and Mitchell [1932] reinvestigated the problem and found that aldehyde slightly reduced the velocity of anaerobic formation of uric acid from xanthine, using methylene blue. But when quinine was used as oxidant they once more obtained evidence for summation with the two substrates.

It is quite clear that this conflicting evidence leaves the question of the identity of the enzymes in an unsatisfactory state. If the two enzymes are identical we have an unusual case of enzyme specificity, namely an enzyme which can activate at once a highly specific purine grouping as well as the aldehyde group. Furthermore, whereas the specificity towards the purine grouping is very great there seems to be no specificity as far as aldehydes are concerned since any aldehyde, aryl or alkyl, can be activated. From the point of view of our knowledge of the mechanism of enzyme reactions the identity of these two enzymes is of great importance.

It would offer a useful example for application—by analogy—to other specificity problems. The question was therefore reinvestigated with a view to clearing up the discrepancies in the literature. In this paper the experimental evidence of Wieland and his co-workers will be considered in detail and it will be shown that their evidence against the identity of the two enzymes is not valid, and fresh lines of evidence will be presented pointing strongly to there being only one enzyme.

#### EXPERIMENTAL.

The enzyme was prepared from Grade A cow's milk by the method of Dixon and Kodama [1926]. In some experiments the enzyme powder was not defatted. It was dissolved in buffer at the beginning of each experiment.

The concentrations of the more frequently used solutions were as follows: phosphate buffer solution 0.25 *M*,  $p_H$  7.2; methylene blue 0.0005 *M*; benzylviologen 0.0005 *M*; quinone 0.001 *M*; hypoxanthine 0.007 *M*; uric acid 0.006 *M* (for the inhibition experiments 0.03 *M* was used); acetaldehyde 20%; salicylaldehyde 0.02 *M*; furfuraldehyde 0.1 *M*; sodium salicylate 0.1 *M*. Purines were dissolved in 0.01 *M* NaOH, the hypoxanthine solution being freshly made up every few days. Salicylaldehyde was generally preferred to acetaldehyde as being less volatile and therefore more reliable for Thunberg and Barcroft experiments.

<sup>1</sup> There were cases in which aldehydes alone were oxidised but the enzymic nature of the oxidation in these cases was doubtful.

The anaerobic experiments were carried out in Thunberg tubes, the hollow stoppers of which were made large and so shaped as to lessen the risk of the substrate boiling over. Except where stated differently, each tube contained 3 ml. buffered enzyme solution, 1 ml. methylene blue,  $x$  ml. substrate and  $1-x$  ml. water or another solution. Sets of 4 tubes were evacuated simultaneously with a water pump.

The aerobic experiments were carried out in Barcroft manometers. After equilibration in the bath the substrate was tipped in from Keilin cups.

The temperature of the thermostat in each case was  $38^{\circ}$ .

#### CONCENTRATION CURVES.

In order to examine critically the evidence against the identity of the two enzymes certain aspects of the kinetics must be considered.

Morgan *et al.* [1922], using whole milk, found that the velocity of reduction of methylene blue was independent of the concentration of hypoxanthine. Dixon and Thurlow [1924, 2], using the caseinogen preparation, varied the concentration more widely and obtained the substrate concentration curve shown in Fig. 1, *B*. They found that the "critical concentration" (the concentration at which inhibition begins) depended on the enzyme concentration. That is to say that, whereas  $0.0006M$  hypoxanthine may be below the critical concentration with a highly active enzyme solution, the same concentration of hypoxanthine may be above the critical point—and cause inhibition—of an enzyme solution of low activity. With the whey preparation of Dixon and Kodama I have obtained the substrate concentration curve in Fig. 1, *A* (although when milk was used a

Fig. 1.

Fig. 2.

Fig. 1. *A*, Substrate concentration curve with hypoxanthine. *B*, Dixon and Thurlow's curve.

Fig. 2. Substrate concentration curve with salicylaldehyde.

curve similar to that of Dixon and Thurlow was obtained). Like Dixon and Thurlow's critical concentration, the optimum concentration was found to vary with enzyme concentration. That is, with a constant substrate concentration the relation between activity and dilution of the enzyme was not linear. For example, with a given concentration of hypoxanthine (optimum for the concentration of enzyme used) the reduction time of methylene blue was 1 min. 30 secs.

Dilution of the enzyme 1 in 3 increased the reduction time not to 4 mins. 30 secs. but to 7 mins. 45 secs. The substrate concentration curve for salicylaldehyde also shows a maximum though it is less marked (Fig. 2). The inhibition of the Schardinger enzyme by excess aldehyde begins at a concentration depending on the enzyme activity and here again the inhibition is more pronounced at lower enzyme activity. Curves showing the variation of enzyme activity with change in dilution are given in Fig. 3. It is noteworthy that neither curve

Fig. 3. Enzyme concentration curves with constant substrate concentration. Quantities as given under "Experimental", using 0.2 ml. hypoxanthine and 0.7 ml. salicylaldehyde.

passes through the origin: which means that, at high dilution, activity falls off rapidly owing to inhibition by excess substrate. (In the figures the velocity is expressed as the reciprocal of the reduction time multiplied by 10,000.)

The bearing of this on Wieland and Rosenfeld's adsorption experiments will now be discussed.

#### ADSORPTION EXPERIMENTS.

Wieland and Rosenfeld [1930] studied the adsorption of xanthine oxidase and the Schardinger enzyme by alumina C<sub>γ</sub> and by calcium oxalate. They determined the ratio of the activities of the two enzymes in their preparation from methylene blue reduction velocities in the presence of xanthine and of salicylaldehyde. They then repeatedly treated the enzyme solution with the adsorbing agent and redetermined the ratio after each adsorption. The ratio was found to change. It was concluded that this change in ratio implied preferential adsorption of one enzyme and hence that the enzymes could not be identical.

These authors defined their unit of activity as the enzyme quantity which reduces methylene blue under given conditions in 5 mins. As it would be laborious to adjust the enzyme quantity in each case to give a reduction time of exactly 5 mins., it seems probable that they actually observed the reduction times and calculated the enzyme units. This calculation involves the assumption that the activity is proportional to the concentration of enzyme. But Fig. 3 shows that such is not the case if the concentration of purine is kept constant.

Now, because the inhibition by excess substrate is more pronounced with purine than with aldehyde, the ratio of the reduction times (and therefore of their reciprocals) should vary with varying enzyme concentration, unless these substrates are present optimally for each particular enzyme concentration. Such variation has been observed experimentally and is shown in Fig. 4. The ratio

Fig. 4. Dependence of ratio on enzyme concentration.

can be varied widely merely by varying the dilution of the enzyme. Hence in experiments in which this ratio is studied, either (a) the enzyme quantity must be adjusted to give a standard reduction time with one substrate and the reduction time with the other substrate observed and compared, or (b) the ratio observed must be corrected for dilution of the enzyme by reference to such a curve as in Fig. 4. One of Wieland and Rosenfeld's adsorption experiments was repeated, with the above precautions. The reduction times of an enzyme solution were determined in presence of hypoxanthine and of salicylaldehyde. Ammonium oxalate and calcium chloride were then added and the precipitate centrifuged off. The reduction times (and hence the ratios) were redetermined

using the centrifugate in various dilutions. The ratio was found to have changed, but the change was exactly that which would be predicted from Fig. 4 if the adsorption had merely reduced the enzyme concentration. The precipitate was then eluted with phosphate buffer at  $p_H$  8.0, as described by Wieland and Rosenfeld, and the ratios were determined at two dilutions and compared with those read off from the standard curve. There was no significant change. Some of the observed ratios are shown in Table I compared with those predicted for known

Table I.

The "predicted ratio" was found for each hypoxanthine reduction time from Fig. 4. Quantities as given under "Experimental", using 0.2 ml. hypoxanthine and 0.7 ml. salicylaldehyde.

	Reduction time		Ratio of reciprocals	Predicted ratio
	Hypoxanthine	Salicylaldehyde		
Unadsorbed material (in centrifugate)	2 mins. 15 secs.	5 mins. 30 secs.	2.5	2.5
	3 " "	7 " 15 "	2.3	2.3
	5 " 10 "	8 " 30 "	1.6	1.7
Adsorbed and eluted material	2 " 30 "	6 " 30 "	2.6	2.4
	7 " "	10 " 45 "	1.5	1.5

reduction times with hypoxanthine. Within limits almost any desired ratio could be obtained before or after adsorption or elution by arbitrarily selecting a given dilution of enzyme solution. But the change in ratio does not give any evidence of a separation of the two enzymes.

With regard to Wieland and Rosenfeld's alleged separation it must be emphasised that

- (a) the separation was only partial and never great;
- (b) unless performed under more controlled conditions the experiments cited lose their significance;
- (c) under such controlled conditions there was no indication of any separation.

## METHOD OF COMPETITION.

Wieland and Macrae [1930] showed that the velocity of reduction of methylene blue with xanthine and aldehyde present together as substrates was greater than with either alone. I have been unable to confirm this additive effect. For instance, in one experiment the reduction times were: with 0.2 ml. hypoxanthine 5 mins. 30 secs., with 0.7 ml. salicylaldehyde 9 mins. 15 secs., and with 0.2 ml. hypoxanthine + 0.7 ml. salicylaldehyde 6 mins. 30 secs. The two substrates appear to be competing for the same enzyme, the reduction rate with both together being intermediate between the rates with either alone.

Wieland and Mitchell [1932] used benzoquinone as hydrogen acceptor and showed that the rate of its reduction by xanthine and acetaldehyde present together as substrates was greater than that with either alone. The experimental evidence for their conclusions is hardly satisfactory for the following reasons.

(1) The xanthine added was only equivalent to the quinone. Naturally on adding acetaldehyde the rate was increased, if more xanthine had been added instead the rate would have been increased. In this method it is essential that the enzyme be saturated with its substrate throughout the reaction.

(2) Their curves, which are reproduced in Fig. 5, clearly demonstrate that with increasing amounts of aldehyde the rate of reduction of quinone was progressively more rapid. They selected a concentration of aldehyde which did not saturate the enzyme and, as shown by their own curves, the addition of more aldehyde also had an additive effect.

Fig. 5. Wieland and Mitchell's curves. A, 2 ml. aldehyde; B, 1 ml. aldehyde; C, 0.5 ml. aldehyde; D, 1 ml. aldehyde + xanthine; E, 0.5 ml. aldehyde + xanthine.

(3) Of the two experiments given, in that with the higher concentration of aldehyde (curve D)—i.e. where the aldehyde concentration approached saturation—the additive effect was patently less, lending support to the above criticisms.

(4) It is noteworthy that in one of the two addition experiments the curves for aldehyde alone (B) and for aldehyde + purine (D) are coincident for the

greater part of the reaction, and only towards the end, *i.e.* when the xanthine is nearly exhausted, is there an additive effect.

(5) An alternative and as reasonable an explanation is that the destruction of enzyme by quinone proceeds with different velocities in the two cases. There is other evidence that purines protect the enzyme from destruction.

As Wieland and Mitchell's results with quinone were inconclusive the experiment was repeated. The substrates—hypoxanthine and salicylaldehyde—were present in optimum concentrations for the particular enzyme strength used, as determined experimentally. The reduction of the quinone was followed in two different ways. In the first method a series of 3 Thunberg tubes was used. Each tube contained 2 ml. enzyme-buffer solution, 1.0 ml. quinone and 0.75 ml. benzylviologen as indicator; the first tube contained 0.25 ml. hypoxanthine, the second 1 ml. aldehyde and the third contained both. It was assumed that the reduction of quinone did not proceed through benzylviologen as an intermediary. The appearance of the first traces of the blue colour of the reduced form of benzylviologen marks the completion of the quinone reduction. The times were: with hypoxanthine 5 mins. 15 secs., with aldehyde 16 mins. 15 secs., and with hypoxanthine + aldehyde 12 mins. 45 secs. These results give no indication of any additive effect.

It might be objected that the presence of the dye affected the results—that the quinone was not being reduced directly but *via* the dye. This was unlikely from considerations of potential but to meet the possible objection the experiment was carried out in another way which was suggested by an early experiment of Dixon [1926]. Enzyme-buffer solution and quinone in the same proportions as in the above experiment were put into the tube shown in Fig. 6 which was

Fig. 6.

Fig. 7.

Fig. 6. Vacuum electrode vessel.

Fig. 7. Competition of substrates, using quinone. A, hypoxanthine; B, salicylaldehyde; C, hypoxanthine + salicylaldehyde.

evacuated and incubated at 38° for 15 mins., equilibrium with the electrode being then reached. The substrate was added and the potential followed against a saturated calomel half-cell, the latter being at room temperature. The agar in the capillary bridge was prevented from being forced into the evacuated vessel

by sintering a plug of powdered glass in the end: it was then filled with agar-KCl containing a suspension of kaolin. The hypoxanthine was added from the glass cup *B*. The stalk *A* rested on the bottom of the tube, the curved foot keeping the cup against the tube wall, minimising the risk of fouling the gold electrode. On inverting the tube the arm *C* prevented immersion of *B* and allowed the substrate solution to drain out. Mixing was complete after three inversions. De-aerated aldehyde was added through the burette. When no aldehyde was used boiled-out water was added in this way as a control. The results of this experiment are shown in Fig. 7. Competition is clearly indicated by the curves.

Competition was also observed anaerobically when the comparatively negative dye Nile blue was employed.

It thus appears that, whether the hydrogen acceptor is Nile blue, methylene blue, quinone or molecular oxygen, provided that the enzyme is saturated with substrate, competition is always observed. These findings would be unlikely if two enzymes were concerned.

#### INHIBITORS.

*Effects of salicylate and formate.* Sen [1931] found that vanillin and piperonal inhibit the aerobic oxidation of hypoxanthine by xanthine oxidase. But aldehydes themselves in these experiments behave at once as hydrogen donors and as inhibitors. In order to avoid this complication the oxidation product of salicylaldehyde, namely salicylate, was tested. The results, which are summarised in Table II, show that it inhibits xanthine oxidase and the Schardinger

Table II.

Quantities as given under "Experimental", using 0.2 ml. hypoxanthine, 0.7 ml. salicylaldehyde and 0.1 ml. salicylate.

	Substrate tipped after	Reduction time	
		Hypoxanthine	Salicylaldehyde
Control—no salicylate	2 mins. 30 secs.	5 mins.	11 mins.
Salicylate in stopper	2 " 30 "	9 " 30 secs.	34 "
"	40 " "	10 " 30 "	38 "
Salicylate in tube	2 " 30 "	8 " 45 "	37 "
"	40 " "	8 " 30 "	27 "

enzyme to approximately the same extent. To determine whether the action of salicylate on the enzyme was one of inhibition or destruction the following experiment was performed. The enzyme was incubated with and without salicylate for 40 mins. before the substrate was tipped in. As shown in Table II there is no indication that the activity of the enzyme is diminished by long contact with salicylate—in fact there is some evidence of increased activity. Neutralised sodium formate also inhibited both enzymes in approximately similar degree. The inhibition of the purine oxidase by the oxidation product of the Schardinger enzyme substrate speaks for identity of the enzymes.

*Effect of uric acid.* Dixon and Thurlow [1924, 2] found that anaerobically both enzymes were inhibited by uric acid. This fact constitutes strong evidence in favour of identity. While it is reasonable to assume that uric acid is not a general inhibitor of dehydrogenases the evidence would gain in force if the assumption were verified experimentally. The most suitable enzyme on which to test the effect of uric acid would be the aldehyde oxidase from potato which has certain properties in common with the Schardinger enzyme although incapable of activating hypoxanthine [Bernheim, 1928]. Both enzymes activate

aldehydes, both reduce nitrate and oxygen directly and in each case some product of the aerobic oxidation rapidly destroys the enzyme. A crude preparation of the oxidase was therefore made as follows. Potato juice was saturated with ammonium sulphate and the precipitate filtered off, washed several times with saturated ammonium sulphate and dissolved in buffer. This solution was filtered and the precipitation was repeated. The precipitate obtained was dissolved in buffer at  $p_H$  7.0 and the resultant brown solution was used for the experiment. Using acetaldehyde, furfuraldehyde and salicylaldehyde as substrates it was found that anaerobically uric acid had no inhibitory effect whatever on the aldehyde oxidase from potato. Uric acid was also completely without effect on the lactic and  $\alpha$ -glycerophosphate dehydrogenases from yeast.

*Effect of 3-methylxanthine.* Prof. Keilin kindly informed me that 3-methylxanthine strongly inhibits xanthine oxidase aerobically and suggested that the effect of this purine on the Schardinger enzyme should be studied. Experiment showed that the aerobic oxidation of salicylaldehyde as well as of hypoxanthine was definitely inhibited (Figs. 8 and 9). The difference in the shapes of the two curves will be dealt with in a later section, but it is noteworthy that the inhibition is pronounced during the first 5 mins. and after that time the control velocity tails off rapidly, pointing to extensive destruction of enzyme.

Fig. 8.

Fig. 9.

Figs. 8 and 9. Inhibition of Schardinger enzyme by 3-methylxanthine.

The right Barcroft manometer cups contained 2 ml. enzyme-buffer solution, and the left (compensating) cups contained 2 ml. buffer. Each cup contained 0.7 ml. salicylaldehyde in a Keilin cup. The right cup of manometer A contained 3-methylxanthine. The purine was dissolved in 0.1 N NaOH, and 0.6 ml. containing 10 mg. was used. The same quantity was titrated with HCl: it was found that 0.05 ml. of the NaOH had been neutralised by the purine, while 0.55 remained in excess. Therefore 0.55 ml. NaOH was added to the right cup of manometer B and to each compensating cup to make the  $p_H$  identical. No alkali was put into the pots for absorption of carbon dioxide.

Coombs [1927] showed that 3-methylxanthine, though not itself oxidised, inhibited the enzymic reduction of methylene blue by hypoxanthine. The results in Table III show that 3-methylxanthine also inhibits the enzymic oxidation of various aldehydes by methylene blue.

Table III.

Quantities as given under "Experimental", using 0.0012 *M* 3-methylxanthine and aldehydes in final concentrations shown. Three different enzyme preparations were used for the several aldehydes.

	Reduction time	
	Without purine	With purine
Acetaldehyde (0.01 <i>M</i> )	2 mins. 30 secs.	41 mins.
Vanillin (0.01 <i>M</i> )	20 ..	73 ..
Salicylaldehyde (0.003 <i>M</i> )	3 .. 30 ..	10 ..

*Preferential inhibition of one enzyme.* From time to time cases have been brought to my notice (private communications) of a reagent which strongly inhibits one enzyme although it has little or no effect on the other. But on careful examination, employing suitable controls, these differences largely vanished. In one case the conditions of the experiment were such that the oxidation of aldehyde was not enzymic. In another case it was claimed that the Schardinger enzyme was completely inhibited by a concentration of 2:4-dinitrophenol which had very little effect on xanthine oxidase [Davidson, unpublished experiments]. The inhibition obtained with formaldehyde was certainly greater than with xanthine or hypoxanthine but it was also greater than with other aldehydes, and in no case was the Schardinger enzyme completely inhibited.

I found that neutralised sodium acetate almost completely inhibited xanthine oxidase (using hypoxanthine) although it had but little effect on the Schardinger enzyme (using salicylaldehyde). However, the inhibition, while still marked, was less when xanthine was used or when the hypoxanthine concentration was high. Further, the inhibition of the Schardinger enzyme was greater with acetaldehyde or furfuraldehyde, while with formaldehyde it was even greater than with xanthine.

In view of these experiences it is urged with cogent reason that claims for the non-identity of the enzymes should not be based on preferential inhibition until the matter has been investigated in great detail and all possible controls performed. Indeed it would appear that convincing proof of non-identity can only be provided by complete separation of the enzymes.

#### PROTECTION OF THE SCHARDINGER ENZYME BY PURINES.

The rate of oxygen consumption by the Schardinger enzyme in presence of an aldehyde falls off very rapidly with time (Fig. 8, curve *B*) and it is in practice impossible to obtain a theoretical uptake before complete destruction of the enzyme sets in. This effect has been attributed to the production of hydrogen peroxide [Dixon, 1925]. Fig. 8, *A* represents the velocity of aldehyde oxidation in presence of 3-methylxanthine. Here the velocity falls off to a much less marked extent, so that after a short time the velocity in presence of the purine is greater than that of the control. The obvious explanation is that the Schardinger enzyme is protected by the purine from destruction by some reaction product.

It was of interest to know whether uric acid exerted a similar protective effect on the Schardinger enzyme. The oxygen uptake by furfuraldehyde in the presence of the enzyme was therefore followed with and without uric acid. The curves in Fig. 10 show that oxidation was still proceeding in the presence of uric acid

Fig. 10. Protection of Schardinger enzyme by uric acid during aerobic oxidation of furfuraldehyde. *A*, with uric acid; *B*, without. The right Barcroft manometer cups contained 2 ml. enzyme-buffer solution, and the left (compensating) cups contained 2 ml. buffer. Each cup contained 0.2 ml. furfuraldehyde in a Keilin cup. The cups of manometer *A* contained 1.1 ml. 0.03 *M* uric acid. Water was added to all cups to adjust the volume to 3.3 ml. No alkali was put into the pots.

when it had practically ceased in the control. Presumably protection is effected by adsorption and the specific adsorption of purines at the active group of the aldehyde oxidase speaks for its identity with the active group of the purine oxidase.

#### THE LIVER ENZYME.

Xanthine oxidase is found in a number of tissues and is invariably accompanied by the Schardinger enzyme, as shown by Morgan [1926]. If these two enzymes are independent it would indeed be extraordinary if they were always present in the same proportions. The ratios of the activities of the two enzymes from liver were therefore compared with the ratio for milk.

Crude xanthine oxidase preparations were made from ox liver in various ways. Preparations *A*<sub>1</sub> and *A*<sub>2</sub> were made by half-saturating an aqueous extract with ammonium sulphate, drying the precipitate and extracting it with ether. *B* was acetone liver. *C*<sub>1</sub> and *C*<sub>2</sub> were made by extracting *B* with phosphate

Table IV.

Details as given under "Experimental", using 0.2 ml. hypoxanthine and 0.7 ml. salicylaldehyde. The "predicted ratio" was found for each hypoxanthine reduction time (using the milk enzyme) by reference to Fig. 4.

Preparation	Reduction time		Ratio of reciprocals	
	Hypoxanthine	Salicylaldehyde	Observed	Predicted
<i>A</i> <sub>1</sub>	9 mins. 15 secs.	16 mins. 30 secs.	1.8	1.3
<i>A</i> <sub>2</sub>	15 "	12 " 15 "	0.8	1.1
<i>B</i>	7 "	15 "	2.1	1.5
<i>C</i> <sub>1</sub>	4 " 20 "	10 " 45 "	2.6	2.0
<i>C</i> <sub>2</sub>	4 " 45 "	10 " 40 "	2.2	1.7
<i>D</i>	4 " 15 "	6 " 30 "	1.5	2.0
Mean			1.8	1.6

buffer, half-saturating with ammonium sulphate and extracting the dried precipitate with ether. *D* was a dialysed aqueous extract. The reduction times of methylene blue with hypoxanthine and salicylaldehyde are shown in Table IV and the ratios are compared with those for milk at corresponding dilutions of enzyme (the criterion of dilution being the reduction time with hypoxanthine) by reference to Fig. 4. The preparations were mostly coloured and had a small reducing blank. The agreement between the ratios found for liver and for milk, though not exact, is striking.

*Colostrum.* Both enzymes were found in two samples of cow's colostrum. One of the samples was taken a few minutes after parturition.

#### EMBRYONIC APPEARANCE OF THE ENZYMES.

Morgan [1930] studied the first appearance of xanthine oxidase in chick embryonic tissues. He found it in the yolk sac on the seventh day and in various other tissues after that time. If the Schardinger enzyme emerged simultaneously with xanthine oxidase in the chick embryo one would have a striking confirmation of identity.

Morgan used Bach's technique in which the tissue is ground in sodium fluoride solution and allowed to stand for a day or more until the reducing blank is negligible. In the present investigation the tissue was washed with water and ground with sand. The fluid was centrifuged off and the residue was suspended in water and again ground with sand. The combined extracts were half-saturated with ammonium sulphate, and after 15 mins. the precipitate was centrifuged off, washed with saturated ammonium sulphate and dissolved in 10 ml. buffer. The experiments were performed within a few hours of opening the eggs. With this technique traces of xanthine oxidase were detected some days earlier than recorded by Morgan. Yolk sac and whole embryo were used for these experiments. It was impracticable to remove the yolk sac earlier than the third day. In order to detect small traces of enzyme both the final volume and the concentration of methylene blue were kept low. The results given in Table V show that the first appearances of the two enzymes are exactly

Table V.

Each tube contained 2 ml. enzyme-buffer solution, 0.15 ml. methylene blue and 0.05 ml. hypoxanthine or 0.08 ml. salicylaldehyde. The blank contained water instead of substrate and in each case the volume was made up to 2.25 ml. with water.

Age in days	Tissue	No. of eggs	Reduction time			Enzyme present	
			Hypo-xanthine	Salicylaldehyde	Blank	Xanthine oxidase	Schardinger
3	Yolk sac	8	30 %*	20 %	$\infty$	+	+
4	"	5	5 hours	8 hours	$\infty$	++	++
6	"	6	20 mins.	50 mins.	3 hours	+++	+++
7	Whole embryo	3	$\infty$	$\infty$	$\infty$	-	-
8	"	2	8 hours	8 hours	8 hours	-	-
9	"	2	12 hours	50 %*	$\infty$	+	+

\* Percentage reduction in 12 hours.

coincident. If all dehydrogenases made their first appearance at the same time the value of this observation would be small. Five other enzymes were therefore tested for and the following were found in the 8-day whole embryo: succinic, lactic, hexosediphosphate,  $\alpha$ -glycerophosphate and glucose dehydrogenases.

## EFFECT OF HEAT.

Xanthine oxidase and the Schardinger enzyme are both more resistant to heat than the majority of dehydrogenases. Dixon and Thurlow [1924, 2] stated that "both enzymes... are destroyed in the same degree by heating for a short time". This observation has been confirmed, an enzyme preparation being heated for varying lengths of time. After heating in a water-bath for an hour at 67° both enzymes were still active although considerable destruction of each had been brought about. More prolonged heating destroyed both. In no case was separation of the enzymes achieved.

## DUAL DESTRUCTION.

As a routine procedure during this investigation when for any reason a preparation of xanthine oxidase became inactive towards hypoxanthine its activity towards aldehydes was also tested. In many such experiments there was never encountered a case either of separation of the enzymes or of individual destruction.

## EFFECT OF INACTIVE PROTEIN ON THE RATIO.

For given conditions the ratio of the activities of the two enzymes is found to vary to some extent in different preparations. The variation is never marked and in general the more protein present the higher the ratio: for instance it is high in a preparation rendered partially inactive through long keeping or by heating. It is reasonable to suppose that with destruction of enzyme inert protein is formed which is still capable of adsorbing the substrate. Thus if adsorption of substrate by inert protein were extensive the concentration remaining in solution might then be suboptimum, and the activity of the enzyme would appear to be low. If the adsorption effects with the two substrates were not identical the ratio would appear to change. This hypothesis was put to experimental test. The reduction time of an enzyme solution with salicylaldehyde was found to increase on addition of boiled enzyme solution. Increasing the aldehyde concentration restored the reduction time to the original value. Increase of the aldehyde concentration of the control had practically no effect. The experiment was repeated using a solution of egg albumin. The results are shown in Table VI. The reduction time with hypoxanthine is almost unaffected by inactive protein whereas that with salicylaldehyde is increased. Consequently the ratio rises as shown in the table.

Table VI.

Quantities: 1 ml. enzyme-buffer solution; 2 ml. buffer, boiled enzyme solution or 4% egg albumin in buffer, others as under "Experimental".

				Reduction time
Enzyme	+ 0.2 ml. hypoxanthine			3 mins. 15 secs.
"	"	"	+ boiled enzyme	3 "
"	"	"	+ albumin	3 " 15 "
"	+ 0.7 ml. salicylaldehyde			8 "
"	"	"	+ boiled enzyme	12 " 15 "
"	"	"	+ albumin	12 "
"	+ 1.0 ml.	"		8 " 30 "
"	"	"	+ boiled enzyme	8 "
"	"	"	+ albumin	8 "
Boiled enzyme solution + salicylaldehyde				$\infty$
Activity ratio of control				2.5
"	"	in presence of boiled enzyme		3.7
"	"	"	albumin	4.1

## MIXED DISMUTATION.

Green *et al.* [1934] showed that isolated dehydrogenase systems cannot react with one another directly: the reaction can only proceed through some intermediary of the type of an oxidation-reduction indicator. They showed, for instance, that, in presence of the respective dehydrogenases, lactate and fumarate would not react anaerobically to form pyruvate unless a suitable oxidation-reduction indicator were added. The indicator was alternately reduced by the lactate system and oxidised by the fumarate system, behaving as a hydrogen carrier. So also formate would only react with nitrate, in presence of the enzymes, to yield nitrite if a carrier were present. Xanthine oxidase + hypoxanthine was linked with the succinic dehydrogenase and with the lactic dehydrogenase systems. Several different preparations of xanthine oxidase (made by the method of Dixon and Kodama [1926]) were used, including one prepared by the author, but in no case was any uric acid produced unless a carrier had been added. These last experiments proved that the xanthine oxidase preparations contained no carrier. Now these findings suggested a possible means of investigating the question of the identity of the Schardinger enzyme and xanthine oxidase, for if the two systems will react without added carrier it is unlikely that two dehydrogenases are concerned.

Accordingly enzyme, salicylate and hypoxanthine were incubated anaerobically. After 5 hours the solution was deproteinised with uranium acetate and tested with Benedict's uric acid reagent and with the phosphotungstic reagent, but no uric acid was detected. Nor was any detected either when the relative concentrations of the reagents were varied or when benzylviologen or methylviologen (indicators with potentials of  $-359$  mv. and  $-446$  mv.) were added as carriers, except traces equivalent to the indicator reduced. The non-production of uric acid even in the presence of a carrier may be due to the irreversibility of the change from acid to aldehyde as catalysed by the Schardinger enzyme. For indeed experiment has shown that the system enzyme-aldehyde-acid-indicator is not reversible regardless of the type of aldehyde tried.

The converse experiment was then performed yielding more promising results. When uric acid and salicylaldehyde were incubated with the enzyme the uric acid almost completely disappeared. Uric acid also diminished when various other aldehydes—acetaldehyde, propionaldehyde, isobutylaldehyde, furfuraldehyde, piperonal—were tried, but the disappearance never proceeded to so great an extent as when salicylaldehyde was used. A series of Thunberg tubes was incubated, each tube containing enzyme, uric acid and salicylaldehyde. The uric acid was estimated at intervals, the results being shown in Table VII. Control

Table VII.

Each tube contained 2 ml. enzyme-buffer solution (or buffer only), 0.4 ml. uric acid, 1 ml. salicylaldehyde, with water to make the total volume up to 5 ml. To one tube 0.1 ml. salicylate was added.

	Incubation time	Uric acid mg.
Enzyme + uric acid + aldehyde	0	0.4
" " "	1 hour	0.3
" " "	2 hours 20 min.	0.2
" " "	6 " 15 "	0.1
" " "	10 "	0.05
" " " + salicylate	6 "	0.2
Uric acid + aldehyde + buffer	15 "	0.4
Enzyme + uric acid	15 "	0.4
Boiled enzyme + uric acid + aldehyde	15 "	0.4

experiments were carried out—the aldehyde replaced by water, the enzyme omitted or boiled—but in no case did the concentration of uric acid decrease. The experiments were repeated several times with five enzyme preparations, always with the same result. Salicylate was found to inhibit the reaction between uric acid and salicylaldehyde. That this was due to inhibition rather than to an effect on the equilibrium of the reaction was shown by the following experiment. When uric acid had largely disappeared from a tube salicylate was tipped in from the hollow stopper in a duplicate tube. After incubation overnight no increase in uric acid was observed over that in the control.

The question arose, what is the fate of the uric acid? Is it reduced to xanthine and hypoxanthine? Or does it, when activated by the enzyme, combine with the aldehyde? Into each of four large vacuum tubes were measured 25 ml. very active enzyme-buffer solution, 10 ml. uric acid and 12 ml. salicylaldehyde. A few drops of octyl alcohol were added to reduce foaming during evacuation and to prevent bacterial growth. After 48 hours' incubation more than 90 % of the uric acid had disappeared. The contents of each tube were deproteinised with uranium acetate. The filtrate was made alkaline with ammonia, and ammoniacal silver nitrate was added. The next day the precipitates were centrifuged off, washed, suspended in water and decomposed with hydrogen sulphide. The solutions were filtered repeatedly until clear. Portions of one solution (which contained some uric acid) were shown to reduce methylene blue in presence of the enzyme with production of more uric acid. It was possible that the reduction was due to a compound between aldehyde and uric acid, the former reducing methylene blue and the latter being liberated, but ferric chloride tests failed to show the presence of hydroxybenzene derivatives in any of the solutions. The three other solutions were then heated with alkaline permanganate, acidified and extracted with toluene. This treatment should oxidise any benzene ring compounds likely to be present (*e.g.* salicylaldehyde or complex containing it) to benzoic acid, the latter being the only aromatic acid likely to be extracted by toluene. The extract was washed with saturated sodium chloride, dried by filtering and titrated with alcoholic NaOH. The titrations were negligible.

In the absence of support for the compound hypothesis attention was turned to possible reduction products of uric acid. To an enzyme-buffer solution were added uric acid, salicylaldehyde and a few drops of octyl alcohol. The mixture was put into flasks which were immediately evacuated and incubated at 45° for 3 days with frequent shaking. The flasks were then cooled and opened. Test showed that the uric acid had nearly all disappeared. The proteins were removed with 10 % trichloroacetic acid and the filtrate was concentrated *in vacuo*. The concentrate was filtered, made alkaline with ammonia and filtered again, and ammoniacal silver nitrate was added. The silver precipitate was filtered off, washed with ammonia and then with water and boiled with nitric acid of sp.gr. 1.1. The solution was filtered hot and allowed to cool. The next day a copious precipitate had formed. This was filtered off and recrystallised twice from nitric acid of sp.gr. 1.1. The crystals were suspended in water and decomposed with hydrogen sulphide. The solution was filtered several times, concentrated on a water-bath and filtered hot. Ammonia was added to the hot solution until the  $p_H$  was 7.6. The solution was then allowed to cool and the precipitate centrifuged off. The substance was recrystallised from water and dried. It had the following properties:

- (1) It was a non-deliquescent white powder.
- (2) Its aqueous solution had a slightly alkaline reaction.

- (3) Analysis showed 39.7 % N (hypoxanthine has 41.2 %)
- (4) With xanthine oxidase it reduced methylene blue rapidly in a vacuum tube.
- (5) Similarly it reduced methylviologen.
- (6) It took up oxygen in the presence of xanthine oxidase.
- (7) Uric acid was produced by incubation with the enzyme and 0.1 % methylene blue.
- (8) Uric acid was produced by aerobic incubation with the enzyme.
- (9) It formed a silver salt insoluble in cold dilute nitric acid.

The amount of material available was not sufficient for more thorough purification and elementary analysis, but it is improbable that any compound other than hypoxanthine would give these specific biochemical tests. That milk does not contain any hypoxanthine is shown by the fact that methylene blue is never reduced by fresh milk.

These results may be explained in another way. It is known that xanthine, under the influence of the enzyme, is dismuted to some extent to form hypoxanthine and uric acid. Conversely a mixture of hypoxanthine and uric acid reacts to form some xanthine [Green, 1934]. This equilibrium may be represented by the following equation:

If xanthine oxidase and the Schardinger enzyme are one a similar reaction between the reductant of one enzyme and the oxidant of the other might occur, the reaction proceeding according to the equation

Some of the xanthine should then be dismuted, or react with more aldehyde, forming hypoxanthine. Proof that this does occur is furnished experimentally by the disappearance of uric acid and the isolation of hypoxanthine. The term "mixed dismutation" is suggested for the phenomenon. Numerous controls prove that it only occurs in presence of the enzyme. It has been shown [Green *et al.*, 1934] that isolated dehydrogenase systems only react with one another if an oxidation-reduction indicator or carrier is present, and that there is no carrier in the xanthine oxidase preparation. Therefore the phenomenon of mixed dismutation is presented as evidence that only one dehydrogenase is concerned in the activation of purines and of aldehydes.

#### CONCLUSION.

In this paper several lines of evidence have been presented in favour of the identity of the two enzymes, and in addition the evidence of Wieland and his collaborators against identity has been shown to be invalid for the most part. The present position may be summarised by the statement that either a set of extraordinary coincidences accounts for the similarity in behaviour and invariable mutual accompaniment of the enzymes or that the two enzymes are identical.

This raises the question: what is meant by identity? Do we mean that one and the same active group (or groups) on the enzyme surface activates both substrates? Do we mean that two kinds of active groups are carried by the same colloid? Or again do we mean a combination of both—one common adsorbing group of low specificity as well as two activating groups, one for certain purines and one for all aldehydes? The first and third seem the more probable suggestions but until more is known about the mechanism of enzyme action it is premature

to discuss these questions. Suffice it to say that the same enzyme appears to activate certain purines and all aldehydes, the term enzyme having its generally understood, though vaguely defined, biochemical meaning.

#### SUMMARY.

1. The evidence in the literature for and against the identity of xanthine oxidase and the Schardinger enzyme is collated.
2. A study of the kinetics shows that Wieland and Rosenfeld's adsorption experiments—which formerly had been taken to disprove identity—were insufficiently controlled.
3. Competition and never addition is observed when both substrates are present together.
4. Any reagent inhibiting one enzyme also inhibits the other.
5. Purines not only inhibit the Schardinger enzyme but protect it from destruction.
6. Uric acid does not inhibit the aldehyde oxidase from potato.
7. Experimental support is adduced for the contention that preferential inhibition of one enzyme offers no proof of non-identity.
8. Activity ratios for the milk and for the liver enzymes are closely parallel.
9. In yolk sac and in whole embryo the first appearances of the two enzymes are exactly coincident, but (in the whole embryo) are preceded by several other dehydrogenases.
10. Preferential destruction has never been brought about by heat or other agent.
11. Certain observed changes in the activity ratio in the presence of much protein are accounted for by adsorption of one substrate, leaving suboptimum concentration in solution.
12. "Mixed dismutation" occurs between uric acid and aldehyde, with disappearance of uric acid and formation of hypoxanthine, the purine dehydrogenase system reacting directly with the aldehyde dehydrogenase system in the absence of a respiratory carrier.

During the progress of the work many useful criticisms and suggestions have been offered by Dr M. Dixon and Dr D. E. Green, to whom I express my thanks.

# CCVII. THE FORMATION OF HYDROGEN FROM GLUCOSE AND FORMIC ACID BY THE SO-CALLED "RESTING" *B. COLI*. I.

BY ABEL TASMAN AND ARNOLD WILLEM POT.

*From the National Institute for Public Health, Utrecht, Holland.*

*(Received May 25th, 1935.)*

DURING recent years Stickland [1929] and Stephenson and Stickland [1931; 1932; 1933] have published a series of investigations on the decomposition of glucose and formic acid by the so-called "resting" *B. coli*. They concentrated their attention chiefly on the question of the evolution of hydrogen in this reaction and came to the conclusion that their bacterial preparations (*B. coli* grown on casemogen or broth, centrifuged, washed and suspended in buffer solutions) must have contained three different enzymes.

(1) *Dehydrogenase*, an enzyme, which activates the hydrogen atoms in the substrate molecule, provided a suitable hydrogen acceptor is present simultaneously. For example, formic acid dehydrogenase catalyses the reaction  $\text{H}.\text{COOH} + \text{R} \rightleftharpoons \text{RH}_2 + \text{CO}_2$ . In this case methylene blue can serve as a hydrogen acceptor.

(2) *Hydrogenase*, a ferment, which under the same conditions activates molecular hydrogen present in a substrate and conveys it to a suitable hydrogen acceptor. This reaction can be represented by the equations  $\text{H}_2 \rightleftharpoons 2\text{H}$ , and  $2\text{H} + \text{R} \rightleftharpoons \text{RH}_2$ . Here again methylene blue or even molecular oxygen may act as acceptor.

(3) *Hydrogenlyase*, which generates molecular hydrogen from formic acid or glucose in the absence of an acceptor. This reaction is represented as follows for the decomposition of formic acid:  $\text{H}.\text{COOH} \rightleftharpoons \text{H}_2 + \text{CO}_2$ .

However, the authors are not quite consistent in their nomenclature. In one case [1931, p. 213] the decomposition of formic acid into molecular hydrogen and carbon dioxide was ascribed to the combined action of the two enzymes formic dehydrogenase and hydrogenase, while later [1932, p. 715] the same action was supposed to result from formic hydrogenlyase. However, this probably only points to a justifiable change of opinion during the carrying out of the research and in any case it is not of great importance.

The cardinal point in the publications of these authors from our point of view is the fact that they make an important distinction between the formation of molecular hydrogen from glucose and from formic acid, the responsibility for which they ascribe to the enzymes glucose hydrogenlyase and formic hydrogenlyase, respectively. Thus the formation of hydrogen from glucose does not occur *via* formic acid, which is always produced in the fermentation with *B. coli*, but represents an essentially different process.

Like Dienert [1900], Karström [1930] differentiates between constitutive and adaptive enzymes. The former are present all the time in the bacterial cell, independently of the mode of cultivation; the adaptive enzymes, however, are formed only in response to a special stimulus during growth exerted in one medium or another by the substance, which will be decomposed (by "resting" microbes) in subsequent experiments.

Yudkin [1932] has extended this idea somewhat by speaking of constitutive enzymes and those obtained by pure "adaptation" or by "training". The difference between the last two categories is that an enzyme obtained by "training" (*i.e.* cultivation for a more or less extended time in a suitable medium) does not lose or at least only slowly loses, its characteristics when successive generations of the organism are bred in a medium from which the stimulating substance is absent, whilst an adaptive enzyme very soon disappears when the organism is cultivated in a medium without a special enzyme regulator. According to these ideas glucose hydrogenlyase is a constitutive and formic hydrogenlyase an adaptive enzyme.

This essential differentiation between the enzymes, which liberate hydrogen from glucose and formic acid, respectively, is justified on the grounds of the following facts according to Stephenson and Stickland.

(1) When *B. coli* is grown under certain conditions (more or less anaerobic) on caseinogen broth without glucose or formate, then centrifuged, washed and suspended in a suitable phosphate buffer, this suspension produces gas containing hydrogen from glucose but does not attack formate. Only when formate or glucose is present previously (the latter forms formate on decomposition) has a bacterial suspension prepared as stated above the property of decomposing both glucose and formate with the production of gas.

(2) The optimum  $p_{\text{H}}$  for the two enzymes is different, *viz.* 6.2 for glucose hydrogenlyase and 7.0 for the formation of hydrogen from formic acid.

(3) The affinity of the two enzymes towards substrates is unequal, being much greater for glucose hydrogenlyase than for the enzyme which breaks up formic acid.

(4) The formation of hydrogen from glucose occurs instantly without any lag period and takes place linearly, which according to Stephenson and Stickland would not be expected if the formation of hydrogen from glucose took place *via* formic acid.

They state their final conclusion as follows:

"The present state of our knowledge on this point is therefore that the hydrogen from glucose does not come through formic acid and that it is liberated by an enzyme, which is not formic hydrogenlyase; whether it is liberated direct from the glucose molecule or from some other intermediate compound we do not know, though the absolute linearity of the reaction indicates that the former may be true."

A summary of these investigations containing the above conclusion has been given by Miss Stephenson [1933].

Since this view of the decomposition of glucose and the method by which hydrogen is formed is not only contrary to the generally accepted theory of this phenomenon but is also at variance with our own experiments on the fermentation of glucose by both gas-forming and non-gas-forming paratyphoid bacilli, it seemed to us that the question was worth reinvestigation.

In the first place we have investigated how far it is possible to prepare suspensions of *B. coli* which will generate hydrogen from glucose but not from formic acid. The same technique was followed in the preparation of these suspensions as was employed by Stephenson and Stickland.

At first we used Witte peptone as the source of nitrogen in our culture media but later we also employed caseinogen-peptone. The preparation of the latter product was carried out according to directions supplied personally by Stickland. This recipe agrees practically completely with that of Cole and Onslow [1931]. It consists in a digestion of caseinogen dissolved as sodium salt by a very

powerful trypsin preparation. Unless otherwise stated, caseinogen broth was always prepared from cheap commercial caseinogen.

Our first strain of *B. coli* (261) was isolated by allowing a drop of faeces suspension to grow on peptone-agar plates (1 % Witte peptone, 0.5 % sodium chloride and 2 % agar in tap-water) and examining the properties of several transplanted colonies. The second strain (1452) was isolated in exactly the same way on caseinogen-peptone. The *B. coli* strain marked "Stickland" was received from Stickland to whom we again tender our thanks. This strain was originally taken from the National Collection of Type-cultures in London and in all probability, therefore, had been subcultured for several years in artificial culture media. The last two strains (3812 and 3813) were isolated like the first on Witte peptone-agar. The properties of all strains were periodically examined in the usual way.

Since Stephenson and Stickland stated that they allowed their *B. coli* cultures to grow in liquid caseinogen broth in Roux flasks, *i.e.* under practically complete aerobic conditions, while Yudkin on the other hand states that under strictly aerobic conditions glucose hydrogenlyase is formed only to a very slight extent and formic hydrogenlyase is not formed at all, it appeared to us not improbable that the production of the two enzymes was more or less dependent on the aerobic or anaerobic condition of the medium during growth.

Our experiments were carried out in the following way:

#### (1) *Method of cultivation.*

- (a) Aerobic on Witte peptone-agar.
- (b) Aerobic on Witte peptone-agar to which 1 % of glucose was added.
- (c) Aerobic on Witte peptone-agar to which 1 % of calcium formate was added.
- (d) For the greater part anaerobic in Witte peptone solution (1 % peptone, 0.5 % sodium chloride in tap water).
- (e) Like (d) in 3 % Witte peptone broth.
- (f) Like (d) in liquid caseinogen-peptone.
- (g) Aerobic on caseinogen-peptone-agar.
- (h) Aerobic on caseinogen-peptone-agar starting from very pure "Casein-puriss" Gr  bler.
- (j) Like (d) in liquid "Casein-puriss" Gr  bler-peptone.

#### (2) *Preparation of the suspensions.*

After 20-24 hours' incubation the liquid cultures were centrifuged and the solid cultures were suspended in physiological salt solution and then centrifuged. The precipitates so obtained were washed twice with salt solution and finally suspended in a small volume of this liquid.

Since all our *B. coli* strains grew much better on or in caseinogen-peptone than on or in Witte peptone, the suspensions obtained in the former culture medium were usually thicker than those obtained with Witte peptone. However, since the results given below are only of a qualitative character, we did not go to the trouble of diluting all our suspensions to the same density.

#### (3) *Fermentation experiments.*

Stephenson, Stickland and Yudkin used the accurate manometric method, particulars of which are given by Dixon [1934], in their experiments, which were of a quantitative nature. Since we had no such apparatus available, we had to

be content with observing the formation or the non-formation of gas from glucose or formate in the well-known Einhorn fermentation tubes. For this purpose, 15 ml. of the suspension in question were mixed with 15 ml. of 1% sodium formate solution in a phosphate buffer at  $p_{\text{H}}$  7.0 and 15 ml. of the suspension were mixed with 15 ml. of 1% glucose solution in a phosphate buffer at  $p_{\text{H}}$  6.2. The formate and glucose solutions were previously sterilised for 12 mins. at 115°, which causes no loss or decomposition of the sugar. These mixtures were then filled into 10 ml. Einhorn tubes, which were placed in an incubator at 40°. The final result of the fermentation, *i.e.* the formation or non-formation of gas was noted after 24 hours. It was established that when gas was formed, it always consisted of a mixture of hydrogen and carbon dioxide. On account of the purely qualitative nature of these experiments no attempt was made to determine the exact amounts of gas produced but a rough idea of these quantities is given in the following ways:

— no formation of gas. tr, formation of a trace of gas. + definite formation of gas. ++ to +++++, the formation of considerable to excessive amounts of gas. The results of duplicate experiments are given in Table I.

19	25. iv. 35	Caseinogen-peptone-agar <sup>5</sup>	.	.	.	.	.	.	.	.

<sup>1</sup> This strain previously passed nine times through calcium formate.

<sup>2</sup> Strains 261 and 1452 had already been cultivated several times on caseinogen-peptone.

<sup>3</sup> Eight previous transfers on caseinogen-peptone puriss.

In this connection the following remarks should be made:

(1) All suspensions of all strains obtained by growing on caseinogen-peptone ferment formate with the production of gas.

(2) With one exception (No. 12), the same suspensions also produce gas from glucose. In Exp. 13, strain 261, the amount of gas formed with glucose was equal to that formed from formate; in all other experiments gas was produced more quickly and in larger quantities in the formate tubes than in those containing glucose. Since the English investigators always used caseinogen-peptone as the basis of their media, their results are in marked contrast to our own. Since we prepared our caseinogen-peptone exactly in accordance with Stickland's recipe

and also since we found no essential difference between caseinogen-peptone prepared from crude commercial caseinogen and that prepared from very pure "Casein puriss. Grüber," we are not able to explain this discrepancy. It should be stated that our caseinogen-peptone was always free from reducing sugars (lactose or glucose) and formate.

(3) Suspensions prepared with media made from Witte peptone behaved rather differently from those discussed above. The first three experiments (1, 2 and 3) with strain 261 gave the impression that in this case we were dealing with a strain which answered to the type used by Stephenson and Stickland. In these experiments gas was definitely produced from glucose but in very small quantities whilst in the case of formate gas was absent. However, when this strain was transferred to a caseinogen-peptone medium, gas was always formed from formate. If this strain was then transferred again to Witte peptone-agar, (Exps. 10 and 11) it no longer showed its original properties. When these experiments were repeated on strains 3812 and 3813, which were freshly isolated from Witte peptone, we succeeded in obtaining an equal or larger formation of gas from glucose than from formate, though in the latter case it was not absent

<sup>4</sup> After about 4 hours more gas was produced from glucose than from formate, but at the end of 24 hours equal amounts had been produced.

<sup>5</sup> Strain 3812 previously subcultured nine times and strain 3813 four times on caseinogen-peptone.

(Exps. 17 and 18). When the same strains were subsequently inoculated on caseinogen-peptone-agar (Exp. 19), the formation of gas from formate was again much larger than from glucose.

When grown on liquid Witte peptone (1%) (Exps. 7 and 14) gas was produced from glucose but none or at most only a trace was formed from formic acid. However, Exp. 10 in which a 3% Witte peptone solution was used, showed a distinct difference. Fermentations carried out with this suspension agreed entirely with those in which caseinogen-peptone was used as the culture medium.

Surveying the whole of the above experiments we came to the conclusion that by cultivating in or on caseinogen-peptone media we were not able to

obtain suspensions of *B. coli* free from "formic hydrogenlyase", as should have been the case according to Stephenson and Stickland, although in none of these experiments was formate or glucose present in the media used.

The results obtained with experiments with Witte peptone, although less uniform in character, definitely do not point in the opposite direction.

Stephenson and Stickland showed that the decomposition of formic acid took place much more rapidly if the cells were able to multiply rapidly, be it on account of the presence of peptone in the medium or at the expense of dead and autolysed bacteria. One might make the suggestion, therefore, that the formation of gas from formate in our experiments is due to the growth of the micro-organisms in question, but since evolution of gas with formate sets in immediately in all caseinogen-peptone experiments, very often before the Einhorn tubes could be placed in the incubator, this possibility may be disregarded.

In 1931 one of us [Pot, 1932; 1933] isolated, in the course of routine investigation in the bacteriological section of the late Central Laboratory, three strains of *B. paratyphosus*-B, which behaved serologically and biochemically as normal *paratyphosus* strains except in one particular, namely, that they did not possess the property of forming gas from glucose. We discovered a simple means of restoring to such strains of *paratyphosus* bacilli the power of liberating gas from glucose and formic acid by cultivating them for a fairly long period in a medium containing calcium formate [Pot and Tasman, 1932; 1933, 1, 2]. When gas was formed from calcium formate the power of liberating gas from glucose returned simultaneously.

During this investigation a detailed quantitative study was also made of the fermentation of glucose [Tasman and Pot, 1934]. Without going more deeply into the matter, suffice it to say that all strains encountered during the investigation ("non-gaseous" and similar types of *B. paratyphosus* made gas-forming by passage through calcium formate, as well as control strains of *B. typhosus* and *B. paratyphosus*) broke down glucose in essentially the same way but with this one difference that *typhosus* and "non-gaseous" *paratyphosus* strains were unable to decompose the formic acid formed in the fermentation any further, whilst normal and "non-gaseous" types of *B. paratyphosus*, which had been converted into gas-forming types, were able to bring about this decomposition. From these experiments it was most clearly apparent, that in the fermentation of glucose with growing and reproducing bacteria, the liberated hydrogen was completely, or practically completely, derived from the decomposition of formic acid produced as an intermediate (the so-called "formic acid scheme").

At the same time it was demonstrated that under certain conditions a very small proportion of the liberated hydrogen finds its origin in methylglyoxal hydrate, which very probably occurs as an intermediate product in the fermentation of glucose and which breaks down into pyruvic acid and hydrogen (the so-called "pyruvic acid scheme"). The results appear to be in complete agreement with the experiments and conclusions of Scheffer [1928], who investigated in detail the fermentation of glucose by various other representatives of the *coli-typhosus-dysentericus* group.

Thus if there are two enzymes, which are responsible for the formation of hydrogen from glucose, our "non-gaseous" strains should be deficient in both. If they acquire formic acid hydrogenlyase by passage through calcium formate, then at the same time they acquire glucose hydrogenlyase. Thus we must assume that the formate stimulus brings about a simultaneous regulation of both enzymes. This is also contrary to the ideas of Karström, who considers

glucose hydrogenlyase to be a constitutive and formic acid hydrogenlyase to be an adaptive enzyme.

Still another possibility is, that only formic acid hydrogenlyase is regulated by the formic acid stimulus and that now the gas from glucose, contrary to what is usually assumed to be the case in a normal fermentation, is actually formed from formic acid. We must then assume that only our *paratyphosus* strains, which have been converted into gas-forming types, produce hydrogen in the fermentation of glucose by decomposition of formic acid and that "normal" *paratyphosus* and *coli* strains must follow another fermentation scheme in spite of the fact that we were able to establish numerous fermentation balances for these decompositions of sugar by the various strains, which failed to show any essential difference whatever; an assumption which certainly possesses no great degree of probability.

Also Stephenson, Stickland and Yudkin state certain facts, which are not in agreement with their theoretical considerations. The former investigators state that a suspension grown in caseinogen broth with formate develops hydrogen from formate at  $p_H$  7.0 with the same velocity as it is developed from glucose at  $p_H$  6.2; a suspension grown on formate-free caseinogen-peptone, however, does not ferment formate and produces hydrogen from glucose but only at a rate about 15 % of that of the previous suspension. Besides they also found that the production of hydrogen from glucose was always accompanied by the formation of an equivalent amount of carbon dioxide. This points to the formation of this hydrogen from formic acid, which is formed as an intermediate, in which case equal amounts of hydrogen and carbon dioxide must be produced.

Yudkin noted that cultivation on media containing formate always increased the power of producing hydrogen from glucose, although not to the same degree as cultivation in a medium containing glucose. He can only form a picture of this reaction with difficulty because, according to his ideas, the decomposition of formic acid into hydrogen and carbon dioxide is not a reaction from which the living bacterial cell can derive energy. We have shown, however [Pot and Tasman, 1933, 2; 1934], that this fission of the molecule certainly puts energy at the disposal of the cell, which is also a plausible explanation of the fact that a culture of non-gas-producing *paratyphosus* bacteria always shows a large increase in the number of living organisms at the moment when it acquires the power of decomposing formic acid.

Thus, as a result of our experiments and theoretical considerations, we must first assume that the hydrogen produced in the decomposition of glucose by growing and "resting" *coli* bacteria, is, in the majority of cases, the result of the decomposition of formic acid produced as an intermediate. Simultaneously, in a few cases, a small quantity of hydrogen may originate from the decomposition of glucose according to the "pyruvic acid scheme", but the formation of hydrogen in this manner is mostly insignificant.

Further, we consider it undesirable to assume the presence of different enzymes. In this particular we take the standpoint of Kluver [1931] who utters the strongest possible warning against assuming the presence of new, so-called "specific", enzymes for the various oxidation-reduction reactions or hydrogen activation reactions, which seem to make their appearance in the different decomposition reactions.

Finally, we wish to state that in a subsequent publication we hope to elucidate the fermentation of glucose by "resting" *B. coli* from a quantitative standpoint by setting up fermentation balances.

## SUMMARY.

1. On repeating the experiments of Stephenson, Stickland and Yudkin, that is to say by growing bacilli on the same media as they used, we have not been able to confirm their results with regard to the decomposition of glucose and formic acid by "resting" *B. coli*.

2. On the basis of these experimental results and from theoretical considerations we come to the conclusion that the formation of hydrogen from glucose occurs, certainly in the majority of cases, *via* formic acid, which is produced as an intermediate compound, and only under certain conditions, in a small proportion of cases, is it produced by other means.

# CCVIII. THE PRODUCTION OF TRIMETHYL- ARSINE BY *PENICILLIUM BREVICAULE* (*SCOPULARIOPSIS BREVICAULIS*).

BY FREDERICK CHALLENGER AND CONSTANCE HIGGINBOTTOM.

*From the Department of Organic Chemistry, the University, Leeds.*

(Received June 1st, 1935.)

CHALLENGER *et al.* [1933] showed that the volatile odorous product evolved from bread cultures of *Penicillium brevicaulis* containing arsenious acid, sodium methylarsonate  $(\text{CH}_3\text{AsO}(\text{ONa})_2$  or sodium cacodylate  $(\text{CH}_3)_2\text{AsO} \cdot \text{ONa}$ —the so-called Gosio-gas—is trimethylarsine. It was also found that when the arsenical substrate contains an ethyl or heavier alkyl group attached to arsenic, as in the case of ethylarsonic acid  $(\text{C}_2\text{H}_5\text{AsO}(\text{OH})_2$ , a mixed arsine, *e.g.* dimethylethylarsine,  $(\text{CH}_3)_2\text{AsC}_2\text{H}_5$ , is obtained. Challenger and Ellis [1935] established also the formation of dimethyl-*n*-propyl-, dimethylallyl- and methyldiethyl-arsines using bread cultures containing *n*-propylarsonic, allylarsonic and diethylarsinic acids respectively.

This remarkable methylating action is not confined to arsenic. In bread or glucose cultures containing sodium selenate or selenite the mould gives rise to dimethyl selenide [Challenger and North, 1934]. The work of Rosenheim [1902] and of Maassen [1902] and experiments of the present authors which are still in progress render it probable that the intense odour evolved from similar cultures containing potassium tellurite is due to dimethyl telluride. The present paper outlines certain theories which have been put forward to account for this type of biological methylation both by earlier workers and during informal discussions with our colleagues. It also describes experimental work which has been designed to test them.

These theories fall under three main heads according to which the methylating agent of the mould may be (a) formaldehyde, (b) acetic acid, (c) a free methyl group detached from, *e.g.*, choline. In (a) it is necessary to consider two possibilities ( $a_1$ ) that formaldehyde arises from the breakdown of carbohydrate, ( $a_2$ ) that it is formed by deamination of glycine. There is very little published evidence in favour of ( $a_1$ ). Fernbach [1910] states that *Tyrophthrix tenuis* converts dihydroxyacetone, sucrose or starch into methylglyoxal, acetic acid and formaldehyde. The latter was detected with Schiff's reagent and isolated as its condensation product with phenylhydrazine [Wellington and Tollens, 1885]. No M.P. or analysis of this derivative was recorded.

There seem to be no other well-authenticated instances of the production of formaldehyde by the biological decomposition of carbohydrate and this has been pointed out by Emde and Hornemann [1931]. Emde [1929] remarks however that bio-methylation in plants can only be a question of secondary formaldehyde arising from carbohydrate, primary formaldehyde from photosynthesis being only available in the chloroplasts; all other parts of the cell must employ carbohydrate breakdown products for methylation. Two criticisms may be made

regarding these statements. Firstly, formaldehyde may arise from glycine by deaminative oxidation and secondly the production of formaldehyde itself is not essential—glyoxylic acid  $\text{CHO} \cdot \text{COOH}$  could function equally well as a methylating agent. The formation of traces of this acid in cultures of *A. niger* on citric acid, malonic acid and acetates has been demonstrated both by Challenger *et al.* [1927] and by Bernhauer and Scheuer [1932].

In Table III, p. 1770, Exps. 31–35 show that the addition of sodium formate with or without formalin, paraformaldehyde, hexamethylenetetramine or rongalite (sodium formaldehydesulphoxylate) exercises no beneficial effect on the yield of trimethylarsine in liquid cultures.

The results obtained on addition of methyl alcohol are discussed on p. 1771.

As regards ( $\alpha_2$ ) it has been shown by Clarke *et al.* [1933] that dimethylglycine with silver oxide gives dimethylamine, carbon dioxide and formaldehyde. Glycine itself is similarly converted into ammonia, carbon dioxide and water [Herbst and Clarke, 1934] and alanine yields ammonia, acetaldehyde, acetic acid and carbon dioxide. These results are, of course, in agreement with the generally accepted theory of the deamination of amino-acids as developed by the work of Neubauer and Fromherz [1911] and later by Krebs [1933]. Glycine on exposure to sunlight in aqueous solution was found by Ganassini [1912] to give ammonia, carbon dioxide and formaldehyde. Illumination of glycine in nitric acid solution in presence of ferric nitrate gives carbon dioxide, formaldehyde and glyoxylic acid [Benrath, 1911; 1912].

Assuming the intervention of formaldehyde as the methylating agent its reaction with arsenious acid might proceed by a mechanism which has been previously outlined [Challenger *et al.*, 1933] and may be briefly summarised thus:

There is unfortunately no direct evidence in favour of this mechanism. That arsenious acid can react in the tautomeric form  $\text{H} \cdot \text{AsO}(\text{OH})_2$  is well known, sodium arsenite and alkyl halides giving alkylarsonic acids  $\text{R} \cdot \text{AsO}(\text{OH})_2$ . Again acetaldehyde reacts with phosphorous and hypophosphorous acids giving the compounds  $\text{CH}_3\text{CHOH} \cdot \text{PO}(\text{OH})_2$  and  $\text{CH}_3\text{CHOH} \cdot \text{PH} \cdot \text{O} \cdot \text{OH}$  as has been shown by Ville [1891] and by Marie [1904]. Moreover formaldehyde reacts with phosphine and hydrochloric acid to give  $(\text{CH}_2\text{OH})_3\text{PCl}$  [Hoffman, 1921; 1930]. The experimental section contains results which show clearly that *P. brevicaulis* exercises a reducing action on derivatives of quinquivalent arsenic.

Attempts to synthesise hydroxymethylarsonic acid have failed, so this suggested scheme has not yet been tested.  $\beta$ -Hydroxyethylarsonic acid,  $\text{HOCH}_2 \cdot \text{CH}_2\text{AsO}_3\text{H}_2$ , which would be expected to yield ethylarsonic acid and then ethyldimethylarsine, is unaffected in bread cultures.

All attempts to detect the formation of methylarsonic or cacodylic acid or trimethylarsine oxide in the various culture media employed in this work have entirely failed, although several litres of medium were examined.

The suggestion (*b*) that the methyl group of the trimethylarsine is derived from acetic acid appears at first sight to have much to recommend it. Cadet's production of dimethylarsine oxide  $(\text{CH}_3)_2\text{As} \cdot \text{O} \cdot \text{As}(\text{CH}_3)_2$  (cacodyl oxide) and of cacodyl itself by heating sodium acetate and arsenious oxide is a well-known reaction (for references and a historical account see Morgan [1917]).

If acetic acid be the source of the methyl group the reaction can be formulated in two ways:

Methylarsonic acid readily gives trimethylarsine in mould cultures and a possible mechanism was discussed on p. 1758.

Mechanisms (1) and (2) labour under the objection that no, or at any rate very few, examples of the simple decarboxylation of fatty acids to hydrocarbons by micro-organisms are recorded in the literature. Exceptions are the conversion of cinnamic acid into phenylethylene by *A. niger* [Herzog and Ripke, 1908] and the formation of methane from acetic and other aliphatic acids by various bacteria.

Mechanism (2) is formulated as a dehydrogenation and appears more probable. Several experiments have been carried out to obtain some idea as to the possibility of this reaction.

Arsonoacetic and arsonopropionic acids were prepared according to the method of Mulder [1929]. If the biological production of trimethylarsine from arsenious acid normally proceeds by scheme (2) above one would expect arsonoacetic acid in bread cultures of *P. brevicaule* to be readily converted by way of methylarsonic acid into trimethylarsine. Arsonopropionic acid

might similarly be expected to yield ethylarsonic acid  $\text{CH}_3\text{CH}_2\text{AsO}(\text{OH})_2$  and thence dimethylethylarsine [Challenger *et al.*, 1933].

In the latter case the mould was found to produce only minute quantities of arsenical gas which was identified as trimethylarsine. This presumably arose from arsenic acid produced by gradual hydrolysis of the arsonopropionic acid in the cultures. (This readily occurs on heating arsonopropionic acid with water at 110°.) Using sodium arsonoacetate in bread and glucose cultures and the free acid in bread cultures, small quantities of trimethylarsine were detected. The quantities were however so small as to suggest that slight hydrolysis of the arsonoacetic acid had occurred. If decarboxylation and intermediate formation of methylarsonic acid had taken place the yield of arsine might have been expected to be much larger, since of all the arsenic compounds examined during the last four years sodium methylarsonate most readily gives arsine. It may therefore be concluded that these results afford no evidence in favour of the participation of acetic acid according to scheme (2).

The results of these experiments are in agreement with those of Challenger and North [1934] who failed to obtain any dimethyl sulphide from bread cultures containing thiodiglycollic acid  $\text{S}(\text{CH}_2\text{COOH})_2$  indicating the difficulty which the mould experiences in decarboxylating the group  $-\text{CH}_2\text{COOH}$ .

Further, though not conclusive, evidence against the suggestion that reaction (1) or (2) represents the mechanism of methylation is afforded by the fact that addition of sodium formate, propionate or butyrate, or of propionic or butyric acid to bread or glucose cultures containing arsenious oxide gave always pure trimethylarsine, identified as the dimercurichloride. Had reactions analogous to (1) or (2) occurred the trimethylarsine might have been expected to be con-

taminated with arsine, triethylarsine and tripropylarsine respectively, or possibly with dimethylethyl- and dimethylpropyl-arsines, *e.g.*

In this connection it may be mentioned that many of the early workers on the nature of Gosio-gas, *e.g.* Martin [1847], Fleck [1872], Selmi [1874] and Wolf [1887], suggested that it consisted of arsine. In none of our experiments, whether in presence or absence of formate, have we obtained the slightest evidence of the presence of this gas. Even small quantities would be readily detected by the formation of yellowish to brown precipitates in Biginelli's solution, an acid solution of mercuric chloride employed by this worker in his researches on the nature of Gosio-gas [1901].

The interesting suggestion that a methyl group may be detached from a methylated derivative such as choline or some other ammonium base was made by Riesser [1913] in order to explain the assumed formation of dimethyl telluride in the animal body after ingestion of inorganic tellurium compounds [Hofmeister, 1894; Maassen, 1902]. It has however been pointed out by Challenger and North [1934] that the identification of the odorous compound as dimethyl telluride in these animal experiments, though probably correct, is based on entirely insufficient evidence. This does not, however, invalidate the importance of Riesser's suggestion which can be applied equally well to explain the biological methylation of arsenic and selenium by moulds. He states that on heating a mixture of choline chloride or betaine, sodium tellurite and sodium formate (the latter acting as reducing agent) the odour of dimethyl telluride is produced. No further identification of this compound was attempted. The wide occurrence of choline in plants has been emphasised by Schulze and Trier [1912].

Riesser brought forward little or no other evidence in favour of his suggestion, though after injecting rabbits with choline and betaine he observed some increase in the creatine content of the muscle. He suggested that the methyl group of the creatine might be derived from the choline. His attempt to prove the possibility of this reaction by a chemical experiment was not convincing.

It nevertheless appeared desirable to repeat and extend Riesser's experiments on the transfer of methyl groups from choline. When anhydrous betaine was heated with a mixture of sodium tellurite and sodium formate in a stream of carbon dioxide, dimethyl telluride was identified among the volatile products by absorption in benzyl chloride and conversion into dimethylbenzyltelluronium picrate.

In this and some other experiments betaine was used instead of choline chloride in order to exclude the possibility of the evolution of methyl chloride which, acting on sodium tellurite, might produce a compound (*e.g.*  $\text{CH}_3\text{TeO}_3\text{Na}$ ) which could possibly give rise to dimethyl telluride on heating. Using betaine however it appears that the reaction must be due to transfer of a methyl group.

By substituting sodium selenite for sodium tellurite and heating with choline chloride or with betaine in a stream of carbon dioxide, dimethyl selenide was readily detected and characterised as the mercurichloride and the platinochloride [Challenger and North, 1934]. Analogous experiments in which sodium arsenite, sodium formate and choline chloride were similarly heated failed to give any trimethylarsine, although this is very easily recognised [Challenger *et al.*, 1933].

In this connection the work of Willstätter [1902] and of Willstätter and Kahn [1904] should be cited. These authors showed that on heating betaine to  $280^\circ$  it undergoes isomerisation to the methyl ester of dimethylaminoacetic acid and

this reaction has recently been shown by Kuhn and Giral [1935] to hold for the homologous  $\xi$ -trimethylpentadeca- and  $\pi$ -trimethylheptadeca-betaine. These latter authors are of the opinion that the reaction is inter- rather than intra-molecular. Further evidence for this is afforded by our observation that mono-methylaniline is produced on boiling betaine (free from hydrochloride) with aniline for several hours.

Experiments in which choline chloride was added to cultures of the mould on glucose or in which betaine was used as sole source of carbon, both in presence of arsenious oxide, showed no beneficial effect on the yield of arsine. Nevertheless it is not impossible that some ingredient of the cell substance containing a methylated nitrogen atom, may under the special conditions obtaining in the cell, lose a methyl group which, if it be eliminated with a positive charge, could be easily coordinated by the unshared electrons of trivalent arsenic or of quadri-valent selenium and tellurium.

Another possible origin of a free methyl group may be sought in the decomposition, possibly enzymic, of a complex ion formed from glycine and arsenious acid:

This suggestion may possibly have some bearing on the observation of Ackerman [1912] who showed that in the body of the dog nicotinic acid is methylated giving rise to trigonelline, the corresponding betaine, the formation of which is accompanied by that of nicotinuric acid. These results have been confirmed by Komori *et al.* [1926].

It appears not unreasonable to assume that glycine may be concerned in the formation of the first as well as the second of these compounds thus:

It was also shown by Cohn [1893] that  $\alpha$ -picoline is similarly converted by the dog into  $\alpha$ -pyridinuric acid, obviously by way of picolinic acid. One would expect that this change should also be accompanied by the formation of homarin, the corresponding methylbetaine, although this was not detected. Homarin has however recently been isolated by Kutscher and Ackermann [1933] from the muscle of *Arca noae*.

The results quoted above are extensions of the well-known work of His [1887] on the conversion of pyridine into methylpyridinium hydroxide in the body of dogs. Komori *et al.* [1926] have confirmed this for turtles. This base has since been detected in the sea anemone *Actinia equina*.

It was noticed by Hausmann [1904] that the actinia *Aiptasia diaphana* Rapp. when placed in sea-water containing 0.03 mg. of arsenious oxide per 100 ml. evolved a garlic odour which was also noticed when this organism was similarly treated with very dilute sodium tellurite. Sodium selenite produced a mercaptan-like odour. Hausmann regarded this effect as analogous to the results of Gosio [1893; 1897; 1901] and Maassen [1902] with *P. brevicaulis*. He was inclined to attribute it, however, to the brown algae (*Zooxanthellen*) which lived in symbiosis with the actinia. Under the influence of the arsenious acid most of these became detached from the actinia, and when separated were found still to be capable of producing odours with selenite and tellurite.

The odorous compounds were not identified but it appears almost certain that they consisted of alkyl, and probably methyl, derivatives of arsenic, tellurium and selenium.

In this connection it is of particular interest that a rather closely allied organism, *Actinia equina*, contains large quantities of tetramethylammonium hydroxide which is believed to exercise a paralysing (curare) action on the small fish which serve as its food. This organism also contains other highly methylated compounds, e.g. methylpyridinium hydroxide and  $\gamma$ -butyrobetaine (actinine), [Ackermann *et al.*, 1923; 1924]. The related compound trimethylamine oxide occurs in many marine animals [Hoppe-Seyler, 1933].

It appears possible, assuming the actinia *Aiptasia diaphana* to exercise an alkylating action on arsenic, selenium and tellurium apart from the algae with which it is in symbiosis, that this may be effected by the transfer of a methyl group from one of its nitrogenous bases to the metalloid.

Particular interest attaches to a recent observation of Haas [1935] that the seaweed *Polysiphonia fastigiata* evolves dimethyl sulphide very shortly after being gathered. Whether this arises by the breakdown and methylation of cysteine or from methionine, or on the other hand is produced by methylation of the sulphur of the sulphuric esters present in seaweed [Haas and Russell-Wells, 1923] awaits investigation. This result recalls the observation of Henze [1904] that the sponge *Suberites domuncula* gives off an intense odour reminiscent of mercaptan. The odorous product removed in a stream of air was absorbed in sulphuric acid with loss of odour which reappeared on dilution of the acid with ice. Henze was unable to prove the presence of sulphur in the odorous compound but from its behaviour with sulphuric acid it would appear very probable that he was dealing with an alkyl sulphide. (Compare the analogous experimental procedure of Pohl [1904] and Abel [1895] for the investigation of volatile sulphur compounds produced under biological conditions.)

#### EXPERIMENTAL.

The ability to produce trimethylarsine when grown on a suitable nutrient medium containing arsenious oxide appears to be confined to moulds, especially *P. brevicaulis*, although other species have been shown to give the garlic odour but to a very much less extent. [Gosio, 1893; Maassen, 1902; Thom and Raper, 1932.]

A large number of bacterial species have been tested by Emmerling [1896], Abel and Buttenberg [1899], Maassen [1902] and Huss [1914], but in no case was a garlic odour detected during growth in the presence of arsenious oxide. Puntoni [1917] however states that *B. mesentericus vulgatus*, *B. mesentericus ruber* and *B. subtilis* gave garlic odours in presence of sodium cacodylate. We have tested one strain of each of these organisms on glucose meat extract at 37° in the presence of 0.2 % arsenious oxide, sodium arsenate, sodium methyl-arsenate or sodium cacodylate and obtained negative results. It should be

mentioned, however, that our strains of these three bacteria were obtained from the Collection of National Type Cultures at the Lister Institute whereas those employed by Puntoni were isolated from the faeces of patients undergoing treatment with sodium cacodylate.

*B. coli communis* and *B. lactis aerogenes* have also been cultivated in a series of six 1 litre conical flasks containing 200 ml. 2 % glucose, with 1 % peptone and 0.025 % arsenious oxide, and the products aspirated through Biginelli's solution. A similar experiment was made using a stream of nitrogen in place of air. Neither organism under either aerobic or anaerobic conditions gave any trace of trimethylarsine dimercurichloride.

Negative results were also obtained by Emmerling [1896] and Huss [1914] using various yeasts. In this research *Saccharomyces cerevisiae*, *S. carlsbergensis*, *S. monacensis* and "Rasse XII" were grown on beer wort or 5 % glucose-mineral salt solution in the presence of arsenious oxide but no arsenical odour was detected.

Gosio [1901] states that the well-washed mycelium of *P. brevicaule* after growth in the presence of arsenious oxide contains arsenic. No essential difference can be detected in the microscopic appearance of the strain used in this research when grown on 5 % glucose-Czapek-Dox solution with or without 0.2 % arsenious oxide. The arsenic content of the growth from 30-day cultures on 5 % glucose-Czapek-Dox solution has also been determined. The mycelium was well washed with a large volume of water, until the washings were free from inorganic arsenic, and dried at 100°. 6-7 g. of dry mycelium analysed by a slight modification of the method of the Sub-Committee on arsenic determination [1930] contained not more than 0.032 % arsenic.

#### *Experiments illustrating the reducing action of P. brevicaule.*

*Hydroxytrimethylarsonium nitrate.* Two one-litre flasks each containing 150 g. bread crumbs were sterilised, inoculated with a spore suspension of *P. brevicaule*, incubated for 5 days at 30° and treated with 25 ml. of 0.8 % hydroxytrimethylarsonium nitrate, which had been previously sterilised at 120° for 20 minutes, giving a concentration of 0.13 % in the bread. The gases produced from the cultures were aspirated with sterile air through Biginelli's solution for 95 days. The resulting precipitate was frequently removed and fresh Biginelli's solution placed in the absorption bottle. On the 17th day, 0.55 g. of white crystals (M.P. 264° and 264° in admixture with an authentic specimen of trimethylarsine dimercurichloride of M.P. 265°) were removed.

Further deposits of M.P. 263°, 264° and 263-4° were obtained after 32, 48 and 75 days respectively giving a total of 0.87 g. of trimethylarsine dimercurichloride, a yield of 65.4 % calculated on 0.4 g. of the arsonium nitrate.

Two similar, sterilised but uninoculated (control) flasks were similarly treated with the arsonium nitrate and the gases aspirated through Biginelli's solution as before. No precipitate formed during the whole of the 95 days.

*Tri-n-propylarsine oxide.* Tri-n-propylarsine dibromide (kindly supplied by Prof. W. J. Jones, University College, Cardiff) was converted into the oxide by two successive treatments with water and excess of silver oxide followed by evaporation to dryness. The solid which resulted was free from halogen but very deliquescent. It was therefore not analysed but treated with picric acid giving *hydroxy-tri-n-propylarsonium picrate*. (Found C, 40.3; H, 5.5; N, 9.6 %.  $C_{15}H_{24}O_8N_3As$  requires C, 40.1; H, 5.4; N, 9.4 %.)

Four bread flasks were prepared as in the last experiment, two were inoculated as before, and incubated for 4 days at 30° and for 4 days at room temperature.

To each of the four flasks were added 25 ml. of 0.8 % tri-*n*-propylarsine oxide (sterilised in the autoclave). The products from the inoculated and control flasks were separately aspirated by sterile air through Biginelli's solution for 69 days. No mercurichloride was obtained from the control flasks but the mould cultures gave after 9 and 30 days deposits (0.02 and 0.02 g.) both of m.p. 106–7° and 107° (constant) after recrystallisation from alcohol. Yield 4.65 %. During the remaining 30 days no further precipitate was obtained except a trace due to the gradual evolution of ammonia from the cultures.

Tri-*n*-propylarsine monomercurichloride was prepared for comparison. Tri-*n*-propylarsine dichloride m.p. 84.5–85° (Dyke *et al.* [1931] give m.p. 84°) was reduced with arsenic-free zinc and hydrochloric acid and the resulting mixture of hydrogen and tripropylarsine passed into aqueous mercuric chloride giving a product m.p. 106–7° and 107° on recrystallisation as before. (Dyke *et al.* [1931] give m.p. 106° for the monomercurichloride  $(C_3H_7)_3As.HgCl_2$ .) In admixture with the mould product there was no depression of m.p.

One of the uninoculated control flasks which had given no arsine during 74 days was then inoculated with the mould. Growth occurred at ordinary temperature and aspiration during 24 days gave 0.05 g. of tri-*n*-propylarsine monomercurichloride m.p. 106°. The yield in this case was 11.6 % as compared with 4.65 % from two flasks in the earlier experiment.

*Hydroxytrimethylammonium chloride and trimethylamine oxide.* The first-named substance  $(CH_3)_3N(OH)Cl$  was prepared by the method of Dunstan and Goulding [1899] and melted constantly at 213° (decomp.) the m.p. depending somewhat on the rate of heating.

It gave the picrate of const. m.p. 200° (decomp.) for which these authors give m.p. 196–8°; Hantzsch and Hilland [1898] give m.p. 197–8°. Treatment of the chloride with excess of freshly precipitated silver oxide in ice-water, filtration and evaporation gave the hydrated amine oxide m.p. 79–81° on recrystallisation from alcohol.

The hydroxychloride (0.1 g. in 20 ml. sterile distilled water) was added to a culture of the mould grown for 3 days at 30° on 50 g. bread and a similar quantity to sterile uninoculated bread. No odour of trimethylamine was obtained after 41 and 11 days respectively at room temperature.

The amine oxide (0.1 g.) under similar conditions added to a culture grown for 4 days at 30° and one day at room temperature gave no odour in either culture or uninoculated control during 50 days.

*Sodium arsenate.* Four cultures on 150 g. bread were prepared as usual and incubated for 10 days at 30° and 2 days at room temperature. 25 ml. of 1.2 % sodium arsenate were added to each. After 19 and 51 days, 0.2 g. and 0.9 g. of mercurichloride m.p. 264° were obtained. On the 58th day two bottles containing 2:4-dinitrophenylhydrazine in 2*N* HCl were placed in the absorption train followed by Biginelli's solution as usual. No dinitrophenylhydrazone separated but a further deposit of 1.25 g. of mercurichloride m.p. 264° was obtained. Recrystallisation of the united deposits gave plates m.p. 265° not depressing the m.p. (265°) of authentic trimethylarsine dimercurichloride.

*Salts of β-hydroxyethylarsonic acid.* The calcium salt, for which we are indebted to the kindness of Dr H. King, was purified from traces of inorganic arsenic by solution in hot dilute hydrochloric acid and reprecipitation with ammonia, the operation being twice repeated. The sodium salt was prepared in 1.2 % solution by boiling with sodium carbonate. No precipitate was obtained in the acidified sterile solution on rapid passage of hydrogen sulphide for 5 minutes.

Four bread cultures in 1 litre flasks were grown for 2 days at 32° and 4 days at room temperature. 25 ml. of the sterile sodium salt solution were added to each culture and the gases aspirated through Biginelli's solution as usual. No odour was detected and no precipitate obtained even after 44 days. Using similar cultures and comparable concentrations of (a) the original unpurified calcium salt and (b) the sodium salt prepared from it, one or two crystals formed on the delivery tube in (a) and a trace of trimethylarsine dimercurichloride m.p. 262° was deposited in (b) after a few days, but did not increase on continuing the experiment for a total of 76 days. The slight positive result here was clearly due to the trace of inorganic arsenic originally present. Had the mould reduced the  $\beta$ -hydroxyl group to hydrogen the resulting ethylarsonic acid should have given dimethylethylarsine (see p. 1757).

*Effect of compounds containing the group  $-(CH_2)_nCOOH$  on the formation of trimethylarsine.*

In the following experiments the mould was grown on 150 g. sterile bread crumbs in four 1 litre flasks for 4 days at 30° and in (b) for one day more at room temperature and treated with (in addition to the appropriate carboxylic acid or its salt) 25 ml. of 1.2 % aqueous arsenious oxide. The gaseous products were continuously aspirated as usual through Biginelli's solution which was renewed after removal of each deposit.

(a) *Sodium propionate*. To each culture were added 25 ml. of 6 % aqueous sodium propionate (concentration in the bread 1 %). A mercurichloride was deposited by the third day and after 10, 14, 25, 38, 56 and 66 days deposits of 0.015, 0.07, 0.18, 0.21, 0.05 and 0.37 g. were obtained having m.p. 261°, 264°, 265°, 263°, 264-5° and 265° respectively. Yield 11.1 %.

(b) *Propionic acid*. 25 ml. of 6 % propionic acid were added to each of the four flasks and after 17, 21, 34, 47 and 60 days deposits of 0.02, 0.18, 0.21, 0.16 and 0.22 g. having m.p. 263-4°, 265°, 265°, 265° and 265° respectively were obtained; 0.79 g. in all. Yield 9.8 %. Trimethylarsine dimercurichloride melts at 265°, tri-*n*-propylarsine monomercurichloride at 107° (see p. 1764).

(c) *Sodium butyrate*. 25 ml. of the 6 % aqueous solution (sterilised at 120° for 20 minutes) were added to each of the four flasks. The first trace of mercurichloride separated on the third day and after 10, 14, 25, 38, 56 and 66 days deposits of 0.05, 0.15, 0.12, 0.26, 0.05 and 0.45 g. (total 1.10 g. yield 13.7 %) were obtained. The m.p. varied from 264° to 265°. A further quantity of mercurichloride could probably have been obtained but the cultures had become very dry and, as is usual under such circumstances, much ammonia was evolved, so the experiment was discontinued.

*Behaviour of P. brevicaule with sodium propionate or butyrate as sole source of carbon.*

A small seed culture of the mould was first grown on 1 % sodium butyrate containing the inorganic salts of the Czapek-Dox medium employed by Raistrick [1931]. The growth was poor.

500 ml. of the same medium in each of four 3-litre flasks were sterilised at 120° for 20 minutes and inoculated with a portion of the seed culture. After 8 days at 30° a thin surface growth began to form and the culture was removed to room temperature and to each flask 1 g. of arsenious oxide in 60 ml. water (final concentration 0.2 %) was added. Aspiration into Biginelli's solution for 25 days gave only one or two crystals on the delivery tube and there was no

increase in the mould growth. Addition of 2.8 ml. hydrochloric acid in sterile distilled water to each flask did not assist growth or cause any more deposit to form during a further 24 days.

An analogous experiment using 1 % sodium propionate but incubating for 15 days at 30° gave equally unsatisfactory results after 10 days. Addition of 3.16 ml. hydrochloric acid in 20 ml. water effected no improvement during a further 24 days.

*Sodium arsonoacetate.*

(a) The sodium salt of arsonoacetic acid was prepared according to the method of Palmer [1925] and twice recrystallised from water. In acidified aqueous solution it gave no precipitate on passage of hydrogen sulphide for 10 minutes.

To four cultures on 150 g. bread in 1-litre conical flasks grown for 4 days at 32° and one day at room temperature were added 25 ml. of sterile 3 % sodium arsonoacetate. Final concentration 0.5 %. No odour of trimethylarsine and no precipitate in Biginelli's solution were obtained on aspiration for 33 days.

(b) 8 cultures on 100 ml. 2 % glucose-Czapek-Dox salt solution were grown for 6 days at 30° and 25 ml. sterile 4 % solution of sodium arsonoacetate added. Final concentration 1 %. Sterile air was passed over the cultures and through Biginelli's solution. No trimethylarsine dimercurichloride was obtained during 29 days.

*Arsonoacetic acid.*

(a) To four cultures on bread crumbs grown for 3 days at 30° and 2 days at room temperature, were added 25 ml. 6 % arsonoacetic acid. Final concentration 1 %. The acid was dissolved in sterile water and not itself sterilised owing to its tendency to liberate inorganic arsenic on heating with water. Aspiration through Biginelli's solution gave in 31 days 0.04 g.  $\text{Me}_3\text{As} \cdot 2\text{HgCl}_2$  m.p. 263–4° and by the 65th day a further 0.02 g. m.p. 260°. Yield 0.27 %.

(b) This experiment was made exactly as in (a) but with a final concentration of arsonoacetic acid of 0.5 %. 0.37 g.  $\text{Me}_3\text{As} \cdot 2\text{HgCl}_2$  m.p. 263–4° was obtained in 36 days; 0.27 g. m.p. 264–5° by 51st day and 0.03 g. m.p. 260° by 68th day. Yield 6.2 %.

(c) Using cultures grown for 3 days at 30° and 10 days at room temperature and a final concentration of 0.5 % arsonoacetic acid as in (b), no trimethylarsine was formed in 14 days. Although these cultures were 13 days old, numerous other experiments have shown that the mould is still unimpaired in activity after this time.

*Arsonopropionic acid.*

Two series of four bread cultures were grown for 3 days at 30° and one day at room temperature. Arsonopropionic acid (solution in sterile water) was added to give a final concentration 0.5 %. In 50 days only a very small amount of precipitate (barely sufficient for the necessary m.p. determinations) was obtained in the Biginelli's solution in each series and this was shown by m.p. and mixed m.p. to be trimethylarsine dimercurichloride and not the dimercurichloride of dimethylethyl arsine.

*Action of P. brevicaulis on glycine.*

Sterile air was passed over four cultures on 300 ml. of Czapek-Dox medium containing 2 % glycine as sole source of carbon, previously incubated for 6 days at 30°. Volatile products were absorbed in (a) 40 ml. of a mixture of conc. HCl (8 g.) and water (40 ml.) and (b) 30 ml. of Biginelli's solution. In 24 hours traces

of an amorphous finely divided precipitate formed in (b) but did not increase appreciably throughout the experiment. It contained no calomel. Warm, but not cold, NaOH caused blackening but no odour was produced. This might indicate the presence of traces of an alkylphosphine. The amount available was too small for further examination, but from a second set of cultures in which the phosphate content of the Czapek-Dox solution was increased from 0.1 to 0.5 % no similar deposit could be obtained.

After 28 days a strong odour of ammonia was noticed. Evaporation of the acid in (a) gave 0.16 g. of a non-deliquescent solid. This was converted into the platinichloride by evaporation of a portion with aqueous chloroplatinic acid and removing excess of the latter by extraction with alcohol. The residue was dried. (Found Pt, 44.1 %.  $(\text{NH}_4)_2\text{PtCl}_6$  requires Pt 43.96 %.)

After 22 days more the fresh acid in (a) yielded another 1.35 g. of ammonium chloride which was identified as before by analysis of the platinichloride. (Found Pt 43.8 %; calc. 43.96 %.  $\text{PtCl}_4 \cdot 2\text{CH}_3\text{NH}_2\text{HCl}$  requires Pt 41.31 %.) The volatile products clearly contained no alkylamines.

The culture medium still contained glycine, as shown by the deep blue colour with copper sulphate. It had  $p_{\text{H}}$  about 9.0 and an ammoniacal odour. 400 ml. were distilled, the distillate acidified and evaporated. Conversion of the residue into chloroplatinate showed absence of alkylamines. (Found Pt 43.8 %; calc. 43.96 %.)

Distillation of 300 ml. of the acidified culture medium indicated the absence of volatile fatty acids. The residue was added to the remainder of the medium, evaporated and a portion distilled with 80 % NaOH and any volatile matter absorbed in hydrochloric acid. Evaporation left only ammonium chloride. (Found, for the platinichloride Pt 43.9 %; calc. 43.96 %.) Had any betaine been formed by methylation of the glycine this would have eliminated trimethylamine under such treatment.

#### *P. brevicaule and glycine in presence of arsenious oxide.*

The procedure was the same as in the last experiment except that the cultures were incubated for 6 days at 33° and 50 ml. of aqueous 1.2 % arsenious oxide (final concentration 0.2 %) were added to each culture before aeration. Traces of the amorphous white precipitate were obtained in the Biginelli's solution at the beginning of the experiment but the quantity was insufficient for examination. Evaporation of the hydrochloric acid after 28 days gave a trace of solid insufficient for analysis. Aeration was continued for 22 days longer using fresh absorption solutions (a) and (b) when traces of a mercurichloride m.p. 262° and 262° in admixture with unrecrystallised trimethylarsine dimercurichloride (m.p. 261–2°) were obtained. The hydrochloric acid on evaporation gave 0.13 g. of ammonium chloride. (Found, for the platinichloride Pt 43.6 %; calc. 43.96 %.) After removal of the mycelium the medium had  $p_{\text{H}}$  about 8.5 and a faint ammoniacal odour. The distillate obtained from 400 ml. of the medium was acidified, evaporated and converted into platinichloride. (Found Pt 43.85 %; calc. 43.96 %.) The two analyses indicate that ammonia but no methylamines are evolved under the conditions employed. The object of the experiment was to determine whether cultures on glycine afforded better yields of trimethylarsine than the usual bread or glucose media. As this was clearly not the case, the test for betaine (distillation with 80 % sodium hydroxide) was omitted.

*P. brevicaula and alanine.*

Four 1-litre flasks with 200 ml. of sterile Czapek-Dox solution containing 2 % alanine as sole source of carbon were inoculated, incubated for 5 days at 30° and aerated, the volatile products being absorbed in 2 bottles containing dilute hydrochloric acid (1:5) and finally in Biginelli's solution. No precipitate formed in the latter during 54 days. The mould growth was just submerged and there was no aerial mycelium. The dilute acid was evaporated and the non-deliquescent residue converted into the platinichloride. (Found Pt 43.94 %; calc. for  $(\text{NH}_4)_2\text{PtCl}_6$  Pt 43.96 %.) Two of the cultures ( $p_{\text{H}}$  8.5–9.0) after removal of mycelium were evaporated to dryness, no ammonia being evolved. The solid residue (2.5 g.) was distilled with 80 % NaOH; absorption in hydrochloric acid and treatment as usual gave a platinichloride. (Found Pt 43.98 %; calc. Pt 43.96 %.) Neither alkylamines nor compounds of the betaine type are therefore detectable when the mould is grown on alanine.

*Action of P. brevicaula on betaine.*

Four 1-litre flasks each containing 200 ml. of Czapek-Dox solution from which the nitrate was omitted and which contained 1 % betaine as sole source of carbon were inoculated from a seed culture on the same medium and incubated for 14 days at 30°, by which time the growth was still poor. The volatile products were aspirated through dilute hydrochloric acid and Biginelli's solution as usual. No deposit formed in the latter even after 97 days. The acid yielded on evaporation 1 g. of a very slightly deliquescent solid which was extracted with cold alcohol, the solution evaporated and the residue extracted with cold chloroform. The latter yielded a trace of solid giving a picrate sintering at 210–215° and decomposing from 265°. This was apparently mostly ammonium picrate with a trace of some other substance. Trimethylamine picrate melts at 220°. It is clear that betaine is not a good nutrient for the mould. This is confirmed by the next experiment.

*Action of P. brevicaula on betaine in presence of arsenious oxide.*

Four flasks each containing 200 ml. of the modified medium used in the last experiment were inoculated as before and incubated for 14 days at 30° and treated with 25 ml. of 1.6 % arsenious oxide. Aeration and absorbents as before. Deposition of mercurichloride occurred after 11 days but increased only very slowly. After 50 days one flask was removed owing to an accidental contamination. After 53 days the mercurichloride (m.p. 259°) was removed and a further quantity (m.p. 264–5°) on the 76th day. The total amount was very small. No further deposit formed and the experiment was discontinued after 97 days.

The hydrochloric acid gave only 0.25 g. of solid which appeared to be ammonium chloride since it was converted as before into a picrate which had no m.p.

*Discussion of tabulated results.*

In the experiments described in Table I all cultures of *P. brevicaula* were grown on media containing Czapek-Dox salt solution with glucose as the sole source of carbon. When a moderately good mycelium had begun to form, the arsenic compound was added, the cultures connected in series and a continuous stream of sterile air drawn over. The air stream together with any trimethylarsine was passed through acid mercuric chloride (Biginelli's) solution where the arsine was retained as the insoluble dimercurichloride  $\text{Me}_3\text{As} \cdot 2\text{HgCl}_2$ . m.p. 265° (decomp.).

Exps. Nos. 1-12 give the yields of trimethylarsine (calculated on added arsenic compound) using arsenious oxide, and Nos. 13-15 those with other sources of arsenic. In No. 15 the sodium methylarsonate was treated with the calculated amount of hydrochloric acid for half-neutralisation of the disodium salt.

In Exp. No. 4 well-washed lumps of pumice stone were introduced into the medium before sterilisation so that only a very shallow layer of liquid remained unabsorbed. By this means a much greater area of growth was exposed to the

air in relation to the quantity of medium used. The growth however was very thin compared with that usually obtained on a liquid surface.

Exps. Nos. 11 and 12 were set up in the usual way, but the system was only aerated for  $1\frac{1}{2}$ –3 hours per week and after 55 days a current of nitrogen was drawn through to drive out any accumulation of trimethylarsine in the culture flasks. No arsine was obtained. A continuous stream of air was then passed over the cultures for a further 77 days. Arsine formation began immediately and the yield was comparable with that obtained under normal conditions.

All other experiments described in Tables I to IV received continuous aeration. The duration of the experiments as recorded in all these tables dates from the addition of the source of arsenic to the culture.

Exps. Nos. 16–21, Table II, show the yields of trimethylarsine obtained when arsenious oxide was added to cultures of the mould on Czapek-Dox salt solution with various carbon compounds, other than glucose, as the sole source of carbon.

The influence of various simple carbon compounds on the yield of arsine obtained during growth on glucose is shown in Table III. The cultures were grown in the usual way on glucose-Czapek-Dox salt solution and then the carbon compounds added at the same time as the arsenious oxide.

The sodium formate was sterilised in aqueous solution at  $120^{\circ}$  for 20 minutes; methyl and ethyl alcohols added directly using sterile pipettes whilst the other compounds were not sterilised but dissolved in sterile water before addition to the cultures. All solutions containing sugars were sterilised in steam for 30 minutes on each of three successive days and in all other cases, unless specifically mentioned, sterilisation at  $120^{\circ}$  for 20 minutes was employed.

The average yield (Table I) of arsine from arsenious oxide in cultures on glucose-Czapek-Dox salt solution is 0.78 % with limiting values 0.37–1.93 %. It is evident that under the conditions shown in Table III ethyl alcohol, sodium formate and formaldehyde (as various derivatives) with or without formate, have no appreciable influence on the production of arsine.

The average yield in the presence of methyl alcohol was somewhat higher *i.e.* 1.63 % although within the highest value obtained with glucose as the sole source of carbon.

The effect of various nitrogenous compounds with or without glucose on arsine formation from arsenious oxide is shown in Table IV. In Exp. No. 45

betaine was used as the sole source of both carbon and nitrogen but in all other cases the nitrate was not omitted from the Czapek-Dox salt solution. In all experiments the nitrogenous compound was present before inoculation.

Although peptone alone gave a low yield, glucose and peptone together gave by far the greatest yields of trimethylarsine obtained on a liquid medium, the average being 4.87 %, with limiting values 3.14–7.55 %. This was to a certain extent associated with a more extensive growth of the mould.

*Reaction between choline chloride or betaine and arsenite,  
selenite and tellurite.*

IA. *Selenite and choline chloride.* An intimate mixture of anhydrous sodium formate (5 g.), choline chloride (5 g.) and sodium selenite (6 g.) was placed in a 100 ml. round-bottomed flask, which was connected with an absorption train of 3 bottles containing HCl (1:1) and 3 containing saturated aqueous  $\text{HgCl}_2$ . The mixture was strongly heated on a sand-bath in a stream of  $\text{CO}_2$  and the volatile products passed through the absorption train. The acid retained the alkaline vapours whilst a white precipitate (0.50 g.) m.p.  $152^\circ$  (decomp.) formed in the mercuric chloride. This gave yellow mercuric oxide and an odour of alkyl selenide on treatment with dil. NaOH. Recrystallised from much acetone it formed shining crystals m.p.  $155^\circ$  (decomp.) and mixed m.p.  $155^\circ$  with a freshly recrystallised authentic specimen of dimethylselenide monomeric chloride,  $\text{Me}_2\text{Se} \cdot \text{HgCl}_2$ . m.p.  $155^\circ$  (decomp.).

A portion of this product was shaken with dilute sodium hydroxide and ether and the ethereal solution treated with aqueous potassium platinumchloride  $\text{K}_2\text{PtCl}_4$ . Removal of solvent gave yellow crystals, m.p.  $163^\circ$  on one recrystallisation from  $\text{CHCl}_3$  and mixed m.p.  $163\text{--}4^\circ$  with authentic dimethylselenide platinumchloride ( $\alpha$ -form) m.p.  $163\text{--}4^\circ$  [Challenger and North, 1934].

IB. *Selenite and betaine.* This experiment was exactly similar to IA except that betaine (anhydrous base) replaced the choline chloride. 0.54 g. mercurichloride m.p.  $150^\circ$  (decomp.) was obtained. Recrystallisation from acetone gave crystals m.p. and mixed m.p.  $155^\circ$  (decomp.).

IC. *Selenite-betaine without formate.* Equal weights (5 g.) of sodium selenite and betaine in the absence of formate heated in a stream of carbon dioxide gave 2.7 g. white precipitate in the aqueous mercuric chloride. Extraction with much acetone gave about 2.0 g.  $\text{Me}_2\text{Se} \cdot \text{HgCl}_2$  m.p. and mixed m.p.  $154^\circ$ . The fraction insoluble in acetone with warm dilute sodium hydroxide gave a black precipitate, soluble in potassium sulphide, and probably consisted of the double compound mentioned below (IF). It seems that the methylation proceeds better in the absence of formate.

ID. *Selenite-tetramethylammonium hydroxide.* Equal weights (5 g. each) sodium selenite, tetramethylammonium hydroxide and anhydrous sodium formate treated in the usual way gave 0.85 g. mercurichloride m.p.  $150^\circ$  and  $155^\circ$  on recrystallisation from acetone.

IE. *Selenite and glycine.* Equal weights (5 g.) of glycine, sodium selenite and anhydrous sodium formate were treated as in IA. A very small quantity of a white solid m.p. above  $270^\circ$  was deposited in the mercuric chloride. Extraction with acetone gave no trace of  $\text{Me}_2\text{Se} \cdot \text{HgCl}_2$ . With sodium hydroxide in the cold there was no odour of alkyl selenide but alkaline vapours were evolved on warming. Evidently no methylation of selenium occurs using glycine.

IF. *Control.* 5 g. each of sodium selenite and anhydrous sodium formate were treated as before but omitting the nitrogenous compound. The white mercurichloride so obtained had no m.p. With dil. NaOH a yellow precipitate formed

which gradually became black and was then completely soluble in aqueous potassium sulphide. The white solid was probably a double compound of mercuric selenide and mercuric chloride. Dimethyl selenide was therefore not produced.

IIA. *Tellurite and choline chloride*. 5 g. each of anhydrous sodium formate and choline chloride with 4 g. potassium tellurite were treated as in the analogous case with selenite.

A trace of mercurichloride m.p.  $151^{\circ}$  (decomp.) was obtained in the absorption flask. This compound blackened slowly with dilute ammonia and with dilute NaOH gave a yellow precipitate (quickly turning black) and an odour of alkyl telluride. The mercurichloride of dimethyl telluride behaves similarly but the compound is difficult to characterise owing to its insolubility.

IIB. *Tellurite and betaine*. Equal weights (5 g.) of potassium tellurite, anhydrous sodium formate and betaine (anhydrous base) were treated in an atmosphere of carbon dioxide as before but using a modified absorption train i.e. (a) 4 bottles hydrochloric acid (1:1), (b) 2 bottles alcoholic benzyl chloride, (c) 2 bottles Biginelli's solution. This was repeated three times using the same absorption solutions (b) and (c) but changing the acid after each run. A small amount of mercurichloride m.p.  $> 270^{\circ}$  giving an odour of  $\text{Me}_2\text{Te}$  with dil. NaOH was formed. The benzyl chloride solution was extracted with water, the aqueous extract washed with ether and then evaporated to dryness. The solid residue with saturated sodium picrate solution gave a picrate m.p.  $117-18^{\circ}$  on recrystallisation from absolute alcohol, and mixed m.p.  $117-18^{\circ}$  with an authentic specimen of benzyldimethyltelluronium picrate m.p.  $117-18^{\circ}$ .

III. *Arsenite and choline chloride*. 6 g.  $\text{NaAsO}_2$  were heated with 5 g. each choline chloride and anhydrous sodium formate as in I and II but with Biginelli's solution to replace the aqueous mercuric chloride. No  $\text{Me}_3\text{As} \cdot 2\text{HgCl}_2$  was obtained.

A similar experiment, using powdered metallic arsenic in place of sodium arsenite, also gave a negative result. Other experiments were carried out in which (a) sodium arsenite (5 g.) and betaine (5 g.) in the absence of formate and (b) equal weights (5 g.) of sodium arsenite, tetramethylammonium hydroxide and sodium formate were treated as before. No formation of trimethylarsine could be detected. This result was decidedly unexpected and the possibility that both biological and chemical methylations of arsenic may proceed by a different mechanism from that of selenium and tellurium must be borne in mind. In view of the ease with which *P. brevicaule* methylates both selenium and arsenic this suggestion may appear somewhat improbable.

It is, however, perhaps significant that, apart from an observation of Puntoni [1917] (who ascribed a garlic odour in the breath of patients taking sodium cacodylate to the action on this substance of intestinal organisms), there appear to be no well-established instances of the production of arsenical breath, whereas tainted breath is a well-recognised phenomenon in the case of tellurium (see p. 1760).

There is a certain amount of evidence for believing that the formaldehyde mechanism suggested on p. 1758 for the biological methylation of arsenic, involving a tautomeric form of arsenious acid, may not hold for selenium. Strecker and Daniels [1928] find that the product from the action of silver selenite,  $\text{Ag}_2\text{SeO}_3$ , on ethyl iodide is identical in b.p. and optical constants with that obtained from selenium oxychloride,  $\text{SeOCl}_2$ , and sodium ethoxide. They conclude therefore that, unlike sulphurous acid, selenious acid or its salts are not capable of tautomerism to the forms  $\text{H} \cdot \text{SeO}_2 \cdot \text{OH}$  or  $\text{Ag} \cdot \text{SeO}_2 \cdot \text{OAg}$ .

*Enzyme preparations.*

A. *Press juice*. *P. brevicaulis* was grown on Czapek-Dox salt solution containing 2 % glucose and 1 % (Witte) peptone until a firm pellicle had formed, *i.e.* for 9 days at room temperature. The medium was removed and replaced with sterile distilled water for 16 hours and the growth again treated with water for 5 hours. The mycelium was filtered through muslin, again washed and excess moisture removed in a hand press.

To 269 g. pressed mould were added 80 g. each of sand and kieselguhr and the mixture ground for 5–10 minutes in a large iron mortar. The resulting mass was wrapped in a wet filter-cloth (from which excess moisture had been removed in a hand press) and the juice expressed in two fractions, (a) up to a pressure of 100 kg./cm.<sup>2</sup> and (b) 100–300 kg./cm.<sup>2</sup> The juice as it formed was filtered through paper and collected in ice-cooled receivers.

(a) Gave 113 ml. and (b) 55 ml. After standing 3 hours in ice-water the juices were examined separately as follows:

- (a) 1. 100 % juice + 0.4 %  $\text{As}_2\text{O}_3$ .
2. 100 % juice + 0.4 %  $\text{As}_2\text{O}_3$  + 2.0 % glucose.
3. 100 % juice + 0.4 %  $\text{As}_2\text{O}_3$  + 10.0 % glucose.
4. 50 % juice + 50 % phosphate buffer  $p_{\text{H}}$  7.0 + 0.2 %  $\text{As}_2\text{O}_3$  + 2.0 % glucose.
5. 10 % juice + 90 % phosphate buffer  $p_{\text{H}}$  7.0 + 0.2 %  $\text{As}_2\text{O}_3$  + 2.0 % glucose.
- (b) 1. 100 % juice + 0.4 %  $\text{As}_2\text{O}_3$  + 2 % glucose.
2. 50 % juice + 50 % phosphate buffer  $p_{\text{H}}$  7.0 + 0.2 %  $\text{As}_2\text{O}_3$  + 2.0 % glucose.
3. 10 % juice + 90 % phosphate buffer  $p_{\text{H}}$  7.0 + 0.2 %  $\text{As}_2\text{O}_3$  + 2.0 % glucose.

No odour of trimethylarsine was detected during three days nor was any stain obtained on filter-paper soaked in aqueous  $\text{HgCl}_2$  and suspended above the liquid, indicating the absence of hydrogen arsenide.

B. *Acetone-dried mycelium*. *P. brevicaulis* was grown on Czapek-Dox salt solution containing 2 % glucose for 2 days at 30° and 11 days at room temperature. The mycelium was allowed to stand over tap-water for 5 hours, filtered through muslin, washed with water and excess moisture removed in a hand press.

The pressed mass (100 g.) was immediately added to 600 ml. acetone, well stirred for 10 minutes, filtered quickly, again treated with acetone (300 ml.) for 2 minutes, filtered and finally well stirred with 100 ml. ether. After removal of ether by filtration the product was dried at 40° for 24 hours and the resulting mass (25 g.) well ground before use.

The enzyme preparation in concentrations 0.125, 0.25, 0.5, 1.0, 2.0, 5.0 and 10.0 % was added to phosphate buffer solution  $p_{\text{H}}$  7.0 together with 0.2 %  $\text{As}_2\text{O}_3$  and 2 % glucose. Similar tests were made at  $p_{\text{H}}$  6.0 and  $p_{\text{H}}$  8.0 with concentrations of enzyme preparation 0.125 to 2.0 %; also at  $p_{\text{H}}$  7.0 with 2 % enzyme preparation and 5 and 10 % glucose instead of the usual 2 %.

In no case was an odour of trimethylarsine detected during 9 days at room temperature.

A further test was done on a larger scale. To each of four 1-litre conical flasks containing 2 % glucose in 200 ml. phosphate buffer solution  $p_{\text{H}}$  7.0, were added 25 ml. 1.6 %  $\text{As}_2\text{O}_3$  (final conc. 0.2 %) and 2 g. enzyme preparation (final conc.

1 %). The flasks were connected in series and a continuous stream of sterile air was drawn over and through Biginelli's solution. No trace of  $\text{Me}_3\text{As} \cdot 2\text{HgCl}_2$  formed during 18 days' aeration at room temperature. This acetone-dried preparation nevertheless contained active enzymes since the tests after 48 hours gave an immediate precipitate with 2:4-dinitrophenylhydrazine. This was not given in absence of the enzyme preparation or by an aqueous extract of the latter.

C. *Berkefeld filtrate*. Two cultures of *P. brevicaule* on 2 % glucose in 200 ml. Czapek-Dox salt solution were grown for 3 days at 30° and 4 days at room temperature. The medium was filtered through a Berkefeld candle, and the filtrate (shown to be sterile) tested immediately as follows:

(a) 50 ml. filtrate + 0.2 %  $\text{As}_2\text{O}_3$ .

(b) 25 ml. filtrate + 25 ml. phosphate buffer solution containing 2 % glucose + 0.2 %  $\text{As}_2\text{O}_3$ .

(c) 10 ml. filtrate + 40 ml. phosphate buffer solution containing 2 % glucose + 0.2 %  $\text{As}_2\text{O}_3$ .

(d) 5 ml. filtrate + 45 ml. phosphate buffer solution containing 2 % glucose + 0.2 %  $\text{As}_2\text{O}_3$ .

Tests (b), (c) and (d) were made with buffer solutions  $p_{\text{H}}$  6.0,  $p_{\text{H}}$  7.0 and  $p_{\text{H}}$  8.0. No odour of arsine was detected in any test during 8 days at room temperature.

A further series of experiments was made using a concentrated filtrate prepared from similar cultures grown for 3 days at 30° and 7 days at room temperature. The Berkefeld filtrate was concentrated at 40–45° under reduced pressure, to  $\frac{1}{2}$  volume and used immediately as follows:

(a) 25 ml. conc. filtrate + 0.2 %  $\text{As}_2\text{O}_3$ .

(b) 25 ml. conc. filtrate + 25 ml. phosphate buffer solution  $p_{\text{H}}$  7.0 containing 2 % glucose + 0.2 %  $\text{As}_2\text{O}_3$ .

(c) 10 ml. conc. filtrate + 40 ml. phosphate buffer solution  $p_{\text{H}}$  7.0 containing 2 % glucose + 0.2 %  $\text{As}_2\text{O}_3$ .

No odour of arsine was detected in any experiment during 18 days at room temperature.

#### CONCLUSIONS.

The experimental results so far obtained do not enable any definite conclusion to be reached regarding the mechanism of biological methylation either by moulds or in the animal body. Bearing in mind the complexity of the problem this is hardly surprising. Of the three mechanisms suggested on p. 1757 namely participation of (a) formaldehyde, (b) acetic acid, (c) a free methyl group detached from a more complex molecule, there appears to be a certain amount of evidence against (b). This is indicated by the experiments with arsonoacetic, arsonopropionic and thiodiglycollic acids and those in which fatty acids or their sodium salts were added to bread cultures in presence of arsenious acid. It should be remembered however that whereas decarboxylation of arsonoacetic acid might be expected (by analogy with malonic acid) to be easy the same does not necessarily follow in the case of arsonopropionic and arsonobutyric acids where the acidic groups are further apart. That the formation of trimethylarsine from arsonoacetic acid by *P. brevicaule* occurs with much difficulty and sometimes not at all is certainly hard to reconcile with mechanism (b). The non-production of dimethylethylarsine from arsonopropionic acid is not necessarily such strong evidence against the acetic acid theory. The suggestion that, whatever its origin, formaldehyde (or glyoxylic acid) is the methylating agent allows the formation of trimethylarsine to be represented by a relatively simple, and from a chemical

point of view unobjectionable, scheme. The difficulty experienced in the synthesis of hydroxymethylarsonic acid  $\text{HOCH}_2\cdot\text{AsO}_3\text{H}_2$  has so far prevented the application of a possible crucial test, since this compound in mould cultures should undergo reduction to methylarsonic acid and methylation to trimethylarsine.

An attempt to test the capacity of *P. brevicaulis* to effect the reduction of a  $-\text{CH}_2\text{OH}$  group to  $-\text{CH}_3$  was made by growing the mould on a 2 % glucose Czapek-Dox solution containing hydroxymethylphosphonic acid or its monosodium salt  $\text{HOCH}_2\cdot\text{PO}(\text{OH})_2$  [Page, 1912]. No conversion either into a volatile phosphine or into methylphosphonic acid could be demonstrated, although a method for the separation of this acid from the hydroxymethyl compound was devised.

The work of Ackermann [1912] and of Cohn [1893] on the behaviour of pyridinecarboxylic acids in the dog suggests the participation of glycine and of a methyl group according to the scheme outlined on p. 1761. For the elimination of methyl from a methylated nitrogen compound, either free or forming part of a larger molecule, there is again no conclusive evidence. The widespread occurrence of methylated bases free or combined in animal, and especially fish, tissue and the methylating (see however p. 1760) action exercised by many such tissues on sodium tellurite [Hofmeister, 1894] render this hypothesis (c) distinctly attractive. Chemical evidence shows that this elimination may occur (p. 1760).

The results described in the present communication and those of Maassen [1902] and of Smith and Cameron [1933] indicate that it is either impossible or at any rate difficult to obtain active enzyme preparations from the mould. Hofmeister and Maassen showed that whereas the intact, minced or crushed tissue of the liver of dogs and especially the lungs and testicles of dogs and the testicles of fishes readily convert inorganic compounds of selenium and tellurium into odorous substances, presumably (see p. 1760) dimethyl selenide and dimethyl telluride, attempts to obtain an active press juice from the organs failed. Exposure of the tissues to low temperatures had no harmful effect on the activity, but heating at  $40-50^\circ$  or treatment with acids, alkalis, concentrated salt solutions or alcohol destroyed it at once. The methylating process is therefore presumably enzymic, but owing to their failure to obtain active preparations after separation from the tissue both Maassen and Hofmeister concluded that it was definitely bound up with the life of the cell.

The authors thank the Royal Society, the Department of Scientific and Industrial Research and Messrs Imperial Chemical Industries Ltd, for grants.

#### *Addendum.*

During the discussion of a communication by Dr Haas (see p. 1762) at the Oxford meeting of the Biochemical Society in May 1935 it was suggested by Mr G. A. D. Haslewood that the production of dimethyl sulphide from seaweed might possibly depend on the elimination of a methyl group from the quaternary carbon atom in the molecule of a sterol.

Such elimination of alkyl groups from quaternary carbon atoms is known to occur during dehydrogenation of sesquiterpenes [Ruzicka and Stoll, 1922; 1923] and sterol derivatives [Diels and Gädke, 1927] by sulphur or selenium, and if the female hormone folliculin be regarded as arising from cholesterol this elimination must also be effected in the animal body. It is possible however that in nature this occurs by oxidation to carboxyl and loss of carbon dioxide especially since the hexahydrobenzene nucleus to which the methyl group in question is attached in the cholesterol molecule, appears as a benzene ring in folliculin.

The suggestion of Mr Haslewood is however extremely interesting and may give rise to further experimental work since sterols are constituents of mould mycelium.

# CCIX. STUDIES ON CAROTENOIDS<sup>1</sup>.

## I. THE CAROTENOIDS OF *DIOSPYROS* FRUITS.

## II. THE CAROTENOIDS OF *ARBUTUS* FRUITS (*ARBUTUS UNEDO*).

By KARL SCHÖN.

*From the Laboratório de Química-Física e Química biológica  
Universidade de Coimbra, Portugal.*

(Received May 20th, 1935.)

## I. THE CAROTENOIDS OF *DIOSPYROS* FRUITS.

THE plants of *Diospyros* are cultivated in Portugal and Spain in numerous varieties, the fruits of which are very difficult to distinguish. It is desirable to investigate their carotenoid content because of their significance in nutrition.

Karrer *et al.* [1932] have isolated lycopin and zeaxanthin from the fruits of *Diospyros Kaki*.

We are indebted to Prof. Dr Carisso, director of the Botanical Garden of Coimbra for a quantity of fruits of *Diospyros costata* which were collected in an immature state from one tree in November 1934 and kept till maturity in a room at 20°.

The fruits were dried with alcohol, which extracted a small quantity of yellow water-soluble colouring matter, and the carotenoids were then totally extracted with a mixture of light petroleum and acetone. When shaken with light petroleum and alcohol (90 %) the pigment passes entirely into the upper layer, indicating the absence of free xanthophylls<sup>2</sup>. After saponification, however, the greater part of the pigment passes into the lower layer.

The colouring matters contained in the upper layer were adsorbed from a solution in light petroleum on to activated aluminium oxide in the apparatus recently described by Winterstein and Schön [1934]. The developed chromatogram showed four distinct zones, from which we isolated cryptoxanthin, lycopene and  $\beta$ -carotene in the crystalline state and determined the presence of  $\alpha$ -carotene by spectroscopy. The cryptoxanthin, which still contained a small quantity of lycopene, was separated from the latter by a second adsorption.

In the chromatographic analysis of the xanthophyll fraction by means of calcium carbonate a broad yellow uniform zone develops, which fills the greater part of the column and consists of zeaxanthin. The highest part of the column contains a very small zone of intensive yellow colouring distinctly different from that of zeaxanthin. From this zone we have isolated a small amount of a xanthophyll which forms yellow-brown stellate groups of crystals. The spectrum, the reaction with hydrochloric acid (blue coloration with 25 % HCl) and the behaviour on adsorption, show that it consists of violaxanthin.

<sup>1</sup> In this paper we publish results of our studies on the Carotenoids of Portuguese plants, which were carried out under the direction of the Director of the Institute, Prof. Dr A. de Moraes Sarmiento.

<sup>2</sup> As cryptoxanthin accompanies the hydrocarbons at this stage in the upper layer, we cannot decide as to the state of this xanthophyll in the fruit.

It is noteworthy that the main part of the vitamin A activity of *Diospyros* fruits depends on the presence of cryptoxanthin, which forms 70 % of the "hydrocarbon fraction," whilst carotene is only present in small amount. An analogous case is reported by Kuhn and Grundmann [1934, 1] with regard to yellow maize.

An interesting fact in regard to the biogenesis of the carotenoids of *Diospyros* fruits is that more than 90 % of the pigment, *i.e.* zeaxanthin, cryptoxanthin and  $\beta$ -carotene, belongs to the same steric group [Kuhn and Grundmann, 1934, 2], whilst  $\alpha$ -carotene, lycopene and violaxanthin—the structure of the latter being still uncertain—form only a smaller part. Zechmeister and Chohnoky [1934] made similar observations on the colouring matters of the pimento.

#### EXPERIMENTAL.

##### *Isolation of the carotenoids of the fruits of Diospyros costata.*

15 kg. of the ripe fruits were crushed by hand and placed in 5 litres of alcohol for 2 days. The voluminous mass was then strongly pressed, the alcohol running out almost uncoloured. The residue was dried and extracted with 3 litres of acetone and 5 litres of light petroleum, and the acetone removed by washing with water. The solution was then washed 5 times with alcohol (80 %) which did not remove the colouring matter from the light petroleum. The petroleum solution was then concentrated *in vacuo* at 50° to a volume of 200 ml., the solution separated by filtration from several resinous products and saponified by adding 500 ml. of ether and the same volume of 5 % methyl alcoholic KOH, keeping the liquid for 2 days under an atmosphere of nitrogen. After saponification 1.5 litres of ether and then 3 litres of water were added, and the solution was washed free from methyl alcohol and alkali and then evaporated *in vacuo*. The residue was dissolved in 1 litre of light petroleum, and the xanthophylls were extracted from this solution by agitating several times with a total volume of 600 ml. of alcohol (90 %). The light petroleum solution, containing the hydrocarbons and cryptoxanthin, was dried with sodium sulphate and kept in an ice-box for 2 days. After this time the colourless material which had separated was filtered off.

The alcoholic solution, containing the xanthophylls, was mixed with 1.5 litres of light petroleum and the xanthophylls were driven into the latter by pouring in very carefully a large quantity of water. The aqueous layer was extracted with a further 1.5 litres of light petroleum, the latter washed with water, dried with sodium sulphate and kept in the ice-box for several days in the course of which colourless material separated out.

##### *Chromatographic analysis.*

(a) *Hydrocarbons.* The concentrated solution of the hydrocarbons was diluted to a volume of 3 litres and then adsorbed on to activated aluminium oxide. After total adsorption of the colouring matters, the column was washed with a large quantity of light petroleum. Four distinct zones developed:

	First absorption band in light petroleum (B.P. 80°)
	m $\mu$
1. Red-brown very sharp zone	484
2. Red, narrow, very sharp zone	506
3. Orange, more diffuse zone	484
4. Yellow, very narrow and diffuse zone	479

The filtrate contained little colouring matter with the same bands as the fourth zone.

The third and fourth zones were eluted with light petroleum containing 1 % of methyl alcohol—the solution was added to the coloured part of the filtrate and then adsorbed a second time on to activated aluminium oxide. By washing with light petroleum two distinct zones were obtained, an orange one of  $\beta$ -carotene in the higher part and a narrow yellow one of  $\alpha$ -carotene in the lower part of the column. We did not succeed in obtaining the  $\alpha$ -carotene in the pure crystalline state, its quantity being very small. The zone of the  $\beta$ -carotene was eluted and the solution concentrated *in vacuo* to 10 ml. After keeping the concentrate several hours in the ice-box, colourless material separated and was filtered off. The solution was then kept for 2 days in the ice-box after which time  $\beta$ -carotene crystals were observed in addition to many colourless crystals. The precipitate was boiled several times with methyl alcohol to remove the impurities and the carotene was then recrystallised from a mixture of benzene and methyl alcohol (1 : 2); m.p.  $180^{\circ}$  (uncorr. in evacuated tube). Absorption bands: in  $\text{CS}_2$  519,485  $m\mu$ ; in light petroleum (B.P.  $80^{\circ}$ ) 484,452  $m\mu$ .

The second zone of the chromatogram containing lycopene was eluted and the solution concentrated *in vacuo* to 7 ml. After remaining 2 days in the ice-box, crystals of lycopene had separated along with colourless material. The precipitate was filtered off, washed on the filter with a little cold light petroleum and boiled three times with methyl alcohol. After recrystallisation from a mixture of benzene-methyl alcohol (1:1), the lycopene was pure. Absorption bands: in  $\text{CS}_2$  548,508,576  $m\mu$ ; in light petroleum: 506,474  $m\mu$ .

The first zone of the chromatogram, containing cryptoxanthin, was eluted and the solution evaporated *in vacuo*. The residue was dissolved in 200 ml. of ether to which was added the same volume of a concentrated solution of KOH in methyl alcohol, and the mixture was kept for 3 days, being heated to  $35^{\circ}$  for 4 hours at the end of this period. The subsequent distribution of the pigment between light petroleum and methyl alcohol (90 %) showed that no pigment had passed into the lower layer, this being the case with 95 % methyl alcohol as described by Kuhn and Grundmann [1933] for cryptoxanthin. A second chromatographic adsorption was then made and yielded a small amount of lycopene. The cryptoxanthin was adsorbed on to the activated aluminium oxide forming a narrow red zone, above which was a broader slightly-coloured zone, which showed the same absorption bands. The middle zone was eluted and the solution evaporated *in vacuo*. On keeping the residue in the ice-box, it solidified. It was then boiled 3 times with methyl alcohol, which dissolved a large part of the colourless material, and the residue was dissolved in 5 ml. of hot benzene. On adding 10 ml. of methyl alcohol to the hot solution a large part of the colourless material was precipitated and was filtered off. The filtrate was evaporated, dissolved in hot benzene and the same volume of methyl alcohol added. After being kept in the ice-box for 2 days, 50 mg. of cryptoxanthin crystallised out. The crystals were boiled with methyl alcohol and twice crystallised from benzene-methyl alcohol (1 : 1). 35 mg. of pure cryptoxanthin were obtained; m.p.  $166$ – $167^{\circ}$  (uncorr. in evacuated tube). Absorption bands, in  $\text{CS}_2$  518,484,455  $m\mu$ ; in chloroform 495,465  $m\mu$ .

(b) *Xanthophylls*. The fraction containing the xanthophylls was adsorbed from solution in 3 litres of light petroleum on to calcium carbonate. On washing with the solvent a large uniform yellow zone developed, which filled the greater part of the column and was limited above by a small deep yellow zone. This latter was eluted with methyl alcohol, the liquid evaporated *in vacuo* and the residue

boiled several times with light petroleum. The xanthophyll was then crystallised from a little methyl alcohol. About 1 mg. of yellow brown needles was obtained. Absorption bands in alcohol, 476,445  $m\mu$ ; in  $CS_2$ : 502,472  $m\mu$ . In ethereal solution a strong blue colour developed with 25 % HCl, whilst acid of 19.5 % gave no reaction. We believe therefore, that this xanthophyll is identical with violaxanthin.

The middle zone was eluted with methyl alcohol and concentrated to a small volume. On adding the same volume of light petroleum, zeaxanthin crystallised out; this was purified by recrystallisation from methyl alcohol. It forms long yellow leaflets in the shape of swallow-tails; M.P. 210° (uncorr. in evacuated tube). Absorption bands in light petroleum 482,453  $m\mu$ ; in  $CS_2$  519,483  $m\mu$ ; in alcohol 483,452  $m\mu$ .

#### *Colorimetric determination of the pigment.*

In 15 kg. of fresh fruit (1.1 kg. of dry substance) we have found the following quantities:

$\alpha$ -Carotene ...	...	...	5.4 mg.
$\beta$ -Carotene ...	...	...	15 „
Lycopene ...	...	...	5 „
Cryptoxanthin ...	...	...	75 „
Zeaxanthin ...	...	...	180 „

The author wishes to express his acknowledgments to Dr Mendonça of the Botanical Institute of the University of Coimbra for supplying the fruits.

## II. THE CAROTENOIDS OF ARBUTUS FRUITS (*ARBUTUS UNEDO*).

The arbutus is generally cultivated in the Mediterranean countries, its fruits serving both for food and for the preparation of aromatic drinks.

The exterior of the fruit is covered with red cicatrices, which contain an anthocyanin. This may be extracted with alcohol; on the addition of sodium hydroxide the red solution turns to blue-green; with ferric chloride a deep blue colour develops, which after some time turns to violet and then becomes pale.

The flesh of the fruit is coloured yellow by carotenoids, which after drying may be extracted with light petroleum and ether. When the pigment is shaken with light petroleum and alcohol (90 %) the latter remains uncoloured, indicating the absence of free xanthophylls. After saponification with alcoholic potash, however, the greater part of the pigment passes into the alcoholic layer.

Chromatographic analysis of the pigment has shown the presence of diverse carotenoids. The petroleum layer, containing the hydrocarbons and the xanthophylls with only one hydroxyl group, gives after adsorption five zones. The uppermost zone, possessing, after elution, only undefined absorption bands, consists of oxidation products. From the second distinct zone we were able to isolate cryptoxanthin in the pure crystalline state. The third very narrow zone contained lycopene, which, however, we could not isolate in the crystalline state because of its extremely small quantity and because of the great amount of uncoloured contaminants. The last two zones contained  $\beta$ - and  $\alpha$ -carotene, from which we were able to isolate  $\beta$ -carotene in the pure crystalline state, the quantity of the  $\alpha$ -isomeride being very low.

The xanthophyll fraction, which represents about 80 % of the total pigment, proved in the chromatographic analysis to be almost pure violaxanthin.

In addition to violaxanthin we isolated a very small quantity of crystallised xanthophyll, which represents a mixture of zeaxanthin with a little lutein.

Violaxanthin in general occurs in appreciable quantities only in certain flowers, whilst its content in fruits is very meagre. It is therefore surprising to note that it forms the greatest part of the pigment of arbutus fruits. Its isolation presents no difficulty and for this reason arbutus fruits are a convenient source of violaxanthin, although they contain it only in relatively small quantities.

Kuhn and Winterstein [1931] record for violaxanthin a M.P. of 199–199.5° (corr.), while Karrer and Morf [1931] found it 8° higher. Our purest preparations had M.P. 203° (corr. in an evacuated tube).

#### EXPERIMENTAL.

25 kg. of the ripe fruits were crushed by hand and kept for 1 day in 25 litres of acetone (70 %). The mass which had an acid reaction was previously neutralised with potassium carbonate. The acetone, which contained the greatest part of the anthocyanin, was pressed out and the residue (5 kg.) kept in alcohol (95 %) for 1 day, the rest of the anthocyanin and a little carotenoid passing into solution. The pressed and dried residue (4 kg.) was then extracted in several portions with a total of 10 litres of light petroleum and then with 10 litres of ether. The solutions were concentrated *in vacuo* at 40–50° to 200 ml., and filtered from a colourless precipitate; the filtrate was then agitated twice with alcohol (80 %) and twice with alcohol (90 %). At this stage the colouring matter remained in the upper layer. The solution was then evaporated *in vacuo*, the residue dissolved in 200 ml. of ether and this solution saponified by adding the same volume of 5 % methyl alcoholic KOH and keeping under an atmosphere of nitrogen for 1 day. After adding 200 ml. of light petroleum 50 ml. of water, were added, the saponified xanthophylls passing into the alcoholic layer. The upper layer was again shaken four times with 70 ml. of methyl alcohol (80 %), the various methyl alcoholic solutions being shaken once with 50 ml. of light petroleum.

The ether-light petroleum solution was carefully washed with water to avoid emulsification until no longer alkaline and then evaporated *in vacuo*. The residue was dissolved in 2 litres of light petroleum and this solution served for chromatographic analysis.

The chromatographic analysis by means of activated aluminium oxide showed the following zones after washing with 3 litres of light petroleum.

	Absorption bands in light petroleum ( $m\mu$ )	Oxidation products
1. Narrow red zone	—	—
2. Broad sharp yellow-red zone	480,447	Cryptoxanthin
3. Narrow sharp violet-red zone	504,472	Lycopene
4. Broad orange zone	483,452	$\beta$ -Carotene
5. Yellow zone not distinct	473,442	$\alpha$ -Carotene

The filtrate was coloured yellow with a little  $\alpha$ -carotene.

The colorimetric determination of the fractions gave the following result (25 kg. of fresh fruits).

1. Cryptoxanthin	...	...	102 mg.
2. Lycopene	...	...	5 "
3. $\beta$ -Carotene	...	...	60 "
4. $\alpha$ -Carotene	...	...	12 "
(Violaxanthin	...	...	ca. 800 ")

*Cryptoxanthin.* The zone containing cryptoxanthin was eluted with light petroleum containing 1 % of methyl alcohol and saponified a second time with concentrated methyl alcoholic KOH for 3 days, at the end of which it was heated for 4 hours to 40°. It was then washed with water to remove alcohol and alkali, the solution dried over sodium sulphate and the chromatographic analysis made a second time by means of activated aluminium oxide, a small quantity of lycopene being separated. After elution the solution was evaporated. The resinous residue crystallised in the course of 1 day when kept in the ice-box. It was boiled in small portions with a total of 150 ml. of methyl alcohol and dissolved in 3–4 ml. of benzene and to the hot solution were added 15 ml. of methyl alcohol. After some time, cryptoxanthin crystallised in characteristic six-sided leaflets. It was recrystallised twice from a benzene-methyl alcohol mixture (1 : 1) and then had *m.p.* 169° (uncorr. in evacuated tube). Absorption bands<sup>1</sup>: in light petroleum 483,452  $m\mu$ ; in CS<sub>2</sub> 518,458  $m\mu$ .

*$\beta$ -Carotene.* The zones containing the carotenes, after elution, were united, washed with water, dried and separated a second time. The upper uniform zone contained  $\beta$ -carotene. It was eluted, agitated five times with methyl alcohol (90 %), evaporated and kept in the ice-box. After some time, carotene crystallised in addition to colourless matter. The carotene was boiled several times with methyl alcohol, to remove the impurities and then recrystallised from a mixture of benzene and methyl alcohol (1 : 1). 5 mg. of pure product were obtained. *m.p.* 177° (uncorr. in evacuated tube). Absorption bands in CS<sub>2</sub> 520,485  $m\mu$ ; in light petroleum (B.P. 80°) 483,452  $m\mu$ .

*Xanthophylls.* The alkaline methyl alcoholic solutions containing the xanthophylls were diluted with water and extracted with ether. The ethereal solution was evaporated and the residue dissolved in a little chloroform. To this solution, containing about 800 mg. of xanthophyll, light petroleum was added until a permanent opacity was produced, and the mixture was then kept in the ice-box. After 1 day 450 mg. of xanthophyll had crystallised out. The part which remained in solution could be extracted with methyl alcohol (90 %). On diluting with water an oily precipitate was formed, which could not be crystallised.

The crystalline xanthophyll—giving a deep blue colour with strong hydrochloric acid—was dissolved in 150 ml. of benzene and the solution diluted with 450 ml. of light petroleum and adsorbed on a column of calcium carbonate. A broad uniform yellow zone developed below which appeared a narrow orange-yellow zone. The upper zone was eluted with methyl alcohol and the solution concentrated *in vacuo* to 150 ml. and kept in the ice-box. After 1 day yellow crystals had separated, which were filtered off. To the filtrate water was added until a permanent opacity resulted. After being kept for a further day in the ice-box, a second fraction of crystals resulted. After recrystallisation from CS<sub>2</sub> the two fractions gave identical preparations of pure violaxanthin. *m.p.* 203° (corr. in evacuated tube). The xanthophyll gave the colour reactions with acetic acid, picric acid *etc.* as described by Kuhn and Winterstein. Absorption bands in CS<sub>2</sub> 501,469  $m\mu$ ; in chloroform 482,451  $m\mu$ ; in alcohol 472,442  $m\mu$ .

The lower zone was eluted with ether and concentrated to a small volume. After the addition of 5 ml. methyl alcohol 20 mg. of xanthophyll crystallised. It was recrystallised from methyl alcohol, depositing 12 mg. of long oblique leaflets, probably consisting of a mixture of zeaxanthin with a little lutein, in which the former predominates; *m.p.* 201–202° (uncorr. in evacuated tube). The product darkened slightly at 196°. Absorption bands in CS<sub>2</sub> 514,479  $m\mu$ ;

<sup>1</sup> All spectroscopic measurements were made with a Hilger prism spectroscope and a copper sulphate-ammonia filter.

in chloroform 490,459  $m\mu$ . The reaction with strong hydrochloric acid was negative.

The author wishes to express his acknowledgments to Prof. E. P. Basto, Director of the Chemical Institute of the University of Coimbra for the use of a spectroscope.

# CCX. FURTHER EXPERIMENTS ON SURFACE FILMS OF STEROLS AND THEIR DERIVATIVES.

By NEIL KENSINGTON ADAM, FREDERIC ANDERTON ASKEW  
AND JAMES FREDERIC DANIELLI.

*From the Sir William Ramsay Laboratories of Physical and Inorganic Chemistry,  
University College, London, and Imperial Chemical Industries.*

*(Received June 1st, 1935.)*

Most of the compounds of the sterol group form stable unimolecular films when spread on a water surface. As with the long-chain aliphatic substances, the two principal stabilising forces for such films are (a) the anchorage to the water afforded by the strong attraction perpendicular to the surface between the water-soluble or "polar" groups and the underlying water, and (b) the lateral adhesion between the molecules of the film, which is largely, but not wholly, due to the hydrocarbon part of the molecules. In the great majority of cases, surface films of sterols are of the "coherent" type, *i.e.* they show a very small surface vapour pressure, or tendency of the molecules to escape along the surface to form a film of the gaseous or vapour type.

Diagram 1.

Sterols containing a single hydroxyl group in the position occupied by that in cholesterol, *i.e.* at 3 on the modern formula, frequently form very incompressible films with areas per molecule near to 40 sq. Å. This has been shown by Leathes [1923], Adam [1928], Knight [1928], Adam and Rosenheim [1929], Fosbinder [1933], and Danielli and Adam [1934]. In such films there is little doubt that the molecules are standing very closely packed and perpendicular (or very nearly perpendicular) to the surface, the hydroxyl groups at 3 being at the lowest point of the molecules. Measurements on models show that the area of cross-section of a sterol ring system perpendicular to its longest axis is of this order of magnitude; moreover, in the vertical position it is the carbon atom at 3 which is at the lowest point of the molecule, hence as the water-attracting group always attempts to approach the water as closely as possible, a vertical position is more probable with a soluble group at position 3 than at any other. If the molecules are vertical, a low compressibility is to be expected, as no reduction of area can be obtained by altering the tilt of the molecules to the surface. Slight differences in area have been found between various sterols

giving this type of film [Knight, 1928; Adam and Rosenheim, 1929]; the nature of these will be discussed further in this paper.

There are numerous cases, however, where sterols or their derivatives with a single hydroxyl or other water-soluble group at position 3 give a film of much greater area than 40 sq. Å.; such films always have a very much greater compressibility than the type just described.  $\Delta^4$ -Coprostene-3-one ("cholestenone") [Adam and Rosenheim, 1929, p. 27] and the various irradiation products of ergosterol [Rosenheim and Adam, 1929; Danielli and Adam, 1934] are well known cases of this. Such films are coherent and have a small surface vapour pressure. There is little doubt that the molecules are considerably tilted to the vertical, especially at low compressions; the tilt is reduced on lateral compression with a corresponding decrease in area, this giving to the film its high compressibility. Temperature variation has little, if any, effect on the area in these cases.

When the water-soluble groups are in other positions, in other rings than ring 1, areas considerably larger than 40 sq. Å. have always been obtained, the compressibility being also high. It may be difficult to distinguish such films from those substances with polar groups at 3, which give films with tilted molecules; they are usually coherent films.

In a few cases, where there are two or more water-attracting groups, situated far apart in the molecule, so that the molecules might be expected to lie flat in the surface, films of the gaseous type have been found; such include a few substances of the oestrin group [Adam *et al.*, 1932; Danielli *et al.*, 1933].

It was shown by Leathes [1923] and later in more detail by Adam [1928] that cholesterol molecules present in a film of an aliphatic substance which normally forms "liquid expanded" films, have a strong tendency to reduce these films to the condensed state. This is probably due to the bulky, vertically orientated molecules of cholesterol obstructing the oscillatory motions of the hydrocarbon chains which are the cause of the "liquid expanded" state of the films. This obstructive effect is evidence of the rigidity of the greater part of the cholesterol molecules, a property necessitated by their constitutional formulae.

The present study of about thirty substances has been undertaken in order to survey more completely the various types of films obtainable from these substances, in the hope that surface film experiments, which are comparatively easy and rapid to carry out, may afford assistance in elucidating the structure of new members of the group, or in ascertaining rapidly whether any compound contains the sterol type of skeleton or not.

#### METHODS.

The surface pressure has been measured by the instrument of Adam and Jessop [1926], as described by Adam [1930]. The surface potential, *i.e.* the change in contact potential between the water and air caused by the presence of the surface film, was measured by the now well-known technique of using an insulated metal wire, connected with an electrometer, the lower end of the wire being coated with a small amount of polonium and being supported about 1 mm. above the water surface. A valve electrometer was used to measure the potentials, exactly as described by Harding and Adam [1933]. In order to compare the surface potentials for equal numbers of molecules per sq. cm. of the film, the quantity  $\mu$  given by Helmholtz's equation

$$\Delta V = 4\pi n\mu$$

( $\Delta V$  = surface potential in millivolts,  $n$  the number of molecules per sq. cm. in the film) has been calculated and is shown in the figures.

In all cases where collapse or imperfect spreading of the film was suspected, with consequent rendering of the measurement of the area per molecule deceptive, the films were examined with a high power dark ground illuminator fixed in the bottom of the trough and focused on the surface, according to the method of Zocher and Stiebel [1930], the details being as described by Adam [1932]. A fully spread film appears dark, but collapsed film or unspread material appears as bright patches.

The substances were dissolved in carefully purified benzene, or, in a few cases, in a benzene-alcohol mixture (5:2 by volume) and the amounts placed on the surface measured by a micrometer syringe [Trevan, 1925]; occasionally a calibrated dropping pipette was used. They were spread, except where otherwise stated, on  $N/50$  HCl at room temperature.

Models of the molecules were frequently made to obtain a clear picture of their probable size, shape and orientation on the surface. They were constructed of spheres of hard wood, those for carbon and oxygen being 1.5 in. diameter and bored with 4 holes arranged tetrahedrally; hydrogens were represented by 1-in. diameter spheres. This gives a scale of approx. 1 in. to 1 Å. Short pegs permitting the spheres to touch each other were always used.

Experience with such models of substances of known constitution indicates that the molecules in surface films practically never pack into areas smaller than the smallest rectangular figures required to surround the models; also that in the surface films there is always a strong tendency for the molecules to orient so that the water-attracting groups are at, or very near to, the lowest point of the molecules as indicated by the models. Considerably larger areas than those indicated by models packed in this way are not uncommon among aliphatic compounds, but with the sterols they are not often found, except through tilting, which is also indicated by a high compressibility of the films. Such models are often very useful in deciding between possible constitutions; they show, for instance, that the modern formula for the sterols is compatible with the area of about 40 sq. Å., but that the older formula would require at least 54 sq. Å. in any orientation with the hydroxyl group near the water. Measurements on the models can be trusted to give the minimum area which the molecules can occupy within 10%.

The figures show the areas per molecule as abscissae, and as ordinates the surface pressure  $F$ , in dynes per cm., the surface potential  $\Delta V$  in millivolts, and  $\mu$  in E.S.U.  $\times 10^{-21}$ .

#### NEW RESULTS AND DISCUSSION.

*Sterols with a hydroxyl group in position 3.* Fig. 1 shows the data for 6 sterols with the above constitution. The surface pressure curves are generally similar but the limiting areas vary from 37.5 to 44 sq. Å., the compressibilities being small. The *epi*-isomerides tend to occupy slightly more space on the surface than the normal form, though the differences in area at a given surface pressure are not great. There are, however, very marked differences in surface potential between the different sterols, the *epi*-isomerides having a much smaller surface potential than the normal; while the difference between the normal and the *epi*-forms is much greater in cholestanol than in coprostanol.

The above data are in good accord with the now generally accepted theory that the difference between the cholestanol and the coprostanol series lies in the steric arrangement of the linkage between rings I and II, well summarised

Fig. 1. I. Ergosterol. II. Cholestane-3-ol. III.  $\Delta^5$ -Cholestene-3-ol (cholesterol). IV. *epi*Cholestane-3-ol. V. Coprostane-3-ol (coprosterol). VI. *epi*Coprostane-3-ol.

by Rosenheim and King [1934, 3] and Ruzicka *et al.* [1933, 1, 2]. Constructing models with the linkages between rings II and III, and between III and IV of the *trans* type, but the linkage between I and II *cis* for coprostanol and *trans* for cholestanol (the ring I being of the "chair" configuration with cholestanol and "boat-shaped" with coprostanol), diagrammatically represented as above (Diagram II), we have the following data for the models:

	Cholestanol	Coprostanol
Horizontal cross-section of minimum enclosing rectangular parallelepiped	36 sq. Å.	40 sq. Å.

These area measurements on the models are uncertain to about 2 sq. Å., and there is a considerably greater uncertainty in comparing them with the areas actually measured in the films, the molecules may not pack exactly into the area of the enclosing rectangular figure. They do indicate, however, that even with fully saturated sterols, the difference in stereochemical linkage between rings I and II is likely to cause the coprostanol films to occupy an area decidedly greater than the cholestanol. The smaller area occupied by ergosterol, and by one or two of the other unsaturated sterols reported by Adam and Rosenheim [1929], may be due either to the presence of unsaturated linkages in the molecules, or, less probably, to closer packing through some degree of interlocking of the projecting hydrogen atoms.

The large differences in the surface potential and  $\mu$  are probably due to differences in the orientation of the dipoles present in the hydroxyl groups. The relation of  $\mu$  to the dipole moment of the molecules in the film has been much discussed [*cf.* Frumkin and Williams, 1929; Schulman and Rideal, 1931; Adam and Harding, 1932; Adam *et al.*, 1934] without a full interpretation being yet possible. If  $\bar{\mu}$  is the dipole moment of the film molecule, and  $\theta$  the inclination of its axis to the vertical, then  $K\mu = \bar{\mu} \cos \theta$ ,

*i.e.* for a given value of the dipole moment,  $\mu$  depends on the angle of tilt of the axis of the dipole and on  $K$ , the dielectric constant of the surface film. The magnitude of the "dielectric constant" of the surface film is very uncertain; there is some evidence, however, that it does not change much even with quite large changes in packing of the films, and it will be assumed that  $K$  is practically the same for all these very similar films.

Examination of models of cholestanol and coprostanol shows that in both these compounds, of the two carbon valencies available for the —C—O— linkage, one is nearly parallel to the long axis of the molecule, and the other makes approximately a right angle with the axis (109° from the first: unfortunately, owing to some flexibility in this ring, a closer definition of these angles does not appear to be possible). The difference between the normal and the *epi*-forms of these compounds is supposed to be due to the hydroxyl being attached to one or other of these two valencies (the principal qualitative difference between the normal and the *epi*-forms of the sterols being that the latter do not form insoluble compounds with digitonin [*v.* Rosenheim and King, 1934, 1, 2]). This is in agreement with the observed facts that the *epi*-derivatives of cholestanol and coprostanol give very small values of surface potential and  $\mu$ , if we assume that in the normal derivatives the —C—O— link of the hydroxyl is attached to the valency which is approximately in line with the axis of the molecule, and hence will have a maximum, or nearly maximum, vertical component when the molecule is vertical, and in the *epi*-derivatives to the other valency, which, being almost at right angles to the molecule, would have only a small vertical component when the molecule is upright. The negative values

of  $\Delta V$  and  $\mu$  observed for *epicholesterol* suggest that when molecules of this compound are upright in the surface film the dipole is inclined upwards, *i.e.* the negative end is uppermost. Observation of models of this compound show that the —C—O— link can actually have a small upward angle.

For the reasons explained above, these arguments can at present only be qualitative, but if they hold, they afford confirmation of the hypothesis, based on the non-precipitability of these substances by digitonin, that the early irradiation products of ergosterol have their hydroxyls epimerised [Rosenheim and King, 1934, 2]; for example, the value of  $\Delta V$  falls from about 400 mv. for ergosterol to about 200 mv. for lumisterol, the first product of irradiation, this change being accompanied by only a small change in area [Danielli and Adam, 1934].

*Ketones with one carbonyl group at 3.* Fig. 2 shows the data for some compounds of this type. In general the surface pressure-area curves tend to considerably larger areas than those for the corresponding 3-hydroxy-compounds, and the films are much more compressible. The surface potentials and values of  $\mu$  are also considerably greater, and the values of  $\mu$  tend to constant values as the area is diminished.

Fig. 2. 3-Keto-compounds. I. Cholestane-3-one. II. Coprostane-3-one. III.  $\Delta^{4,5}$ -Coprostene-3-one ("cholestenone"). IV. Oxime of "cholestenone." V. "Cholestenone" on 0.1% neutral  $\text{KMnO}_4$  solution.

Cholestane-3-one, the ketone corresponding to cholestane-3-ol (cholesterol) and *epicholesterol*-3-ol, occupies an area a few sq. Å. larger than either of these compounds. The molecule is thus probably slightly tilted at low compressions, being brought upright as the pressure is increased.

As in the hydroxyl compounds there is an increase in area corresponding to the more bulky *cis*-linking of rings I and II in passing from the ketone derived from cholestane to that derived from coprostane, but with the ketones the difference is much more marked, coprostane-3-one occupying some 6–8 sq. Å. more than cholestane-3-one.

The unsaturated compound  $\Delta^{4,5}$ -coprostene-3-one (formerly called cholestenone) occupies still larger areas, reaching 59 sq. Å. at zero compression, and

the value of  $\mu$  rises to  $900 \times 10^{-21}$  E.S.U. The large area occupied by this compound was observed by Adam and Rosenheim [1929], who further found that the area occupied by the corresponding oxime was much smaller, as shown in Fig. 2. The increase in the minimum area of the molecule, as measured on models, caused by the *cis*-linkage of rings I and II is insufficient in itself to account for the large areas shown by these ketones; the limiting area observed in the film (59 sq. Å. for coprostenone) is nearly 50% greater than the minimum area required by the models (about 40 sq. Å.). That this increase in area is almost certainly due to a tilt of the molecules is shown by the following experiments (Fig. 3). Mixtures of coprostenone ("cholestenone") and cholesterol in known proportions were spread on a water surface, and the areas occupied by the coprostenone molecules calculated from the experimental figures, assuming that the cholesterol occupied the same areas in these films as when in a film alone. From the curves in Fig. 3 it is seen that the area occupied by coprostenone in such mixtures is considerably reduced, and that in the 1:1 mixture, under 15 dynes per cm. pressure, its area is similar to that of cholesterol itself, indicating that in these films the coprostenone molecule is being held upright by the upright cholesterol molecules, and hence that in the films of coprostenone alone the large areas are due to tilt of the molecules. The surface potentials of these mixed films are plotted against the mean area per molecule, of either kind, and are much closer to the surface potential of coprostenone itself than to that of cholesterol; the meaning of this is, however, not easy to see.

Fig. 3. Cholesterol-coprostenone mixed films. I. Cholesterol. II. Coprostenone. III. Mixed films, ratio  $\frac{\text{one}}{\text{ol}} = 1$ . IV. Mixed films, ratio  $\frac{\text{one}}{\text{ol}} = 3$ .

The reason why the ketones should be so much tilted remains to be explained. If the carbonyl group is not in line with the axis of the molecule (as a first approximation one would expect it to be attached at an angle midway between those of the  $\text{—C—O—}$  links of coprostanol and *epi*coprostanol since it is attached by both these valencies, *i.e.* making an angle approaching  $45^\circ$  with the axis of the molecule), this may account for some of the increase in area, since under zero compression one would expect the molecules to orient themselves with the

dipole vertical. On this view, however, the molecules should be brought upright as the pressure is increased and the dipoles tilted; the values of  $\mu$  do not support this, since they tend to give constant values on compression. Other observed facts in connection with coprostenone for which explanation is at present lacking are the reversion of the oxime to a comparatively small area and the observation that on solutions of neutral  $\text{KMnO}_4$  this compound again shows a diminished area (tending to 56 sq. Å. on 0.02%, to 51 sq. Å. on 0.1% and 0.5%, Fig. 2).

*Monohydroxy- and monoketo-compounds having the polar groups in positions 6 or 7.* The data are given in Fig. 4 for cholestane-6-ol,  $\Delta^4$ -coprostenone-7-ol ("ψ-cholesterol"), and cholestane-6-one. The surface pressure-area curve of cholestane-6-ol shows some resemblance to those of the 3-hydroxy-compounds described above, but the film occupies a larger area and is considerably more compressible. Models of this compound show that here the hydroxyl group can only be in contact with the water surface if the molecule is considerably tilted, and the limiting area given by such models, 48 sq. Å., is in good agreement with the experimentally found limiting area of about 50 sq. Å. The values of  $\Delta V$  and  $\mu$  are lower than for the 3-hydroxy-compounds in which the dipole is nearly

Fig. 4. I. Cholestane-6-ol. II. Cholestane-6-one. III.  $\Delta^4$ -Coprostenone-7-ol ("ψ-cholesterol").

perpendicular, and the value of  $\mu$  diminishes on compression; these data suggest that the hydroxyl group is inclined to the surface even under low compressions and is tilted still further as the molecules are crowded together. Variation of temperature has a slight effect on the areas occupied by the films of this compound, the limiting area being increased by about 1.5 sq. Å., when the temperature of the underlying solution was raised from 17° to 30°, and decreased by a similar amount by cooling to 3°. Experiments were also carried out, similar to those described above in connection with coprostenone, in which mixtures of cholestane-6-ol and cholesterol were spread on a surface. In this case however, in contrast to the behaviour of coprostenone, cholestane-6-ol retained its normal area in the mixed films. This is to be expected, since, though the larger area is again due to a tilt of the molecule, the tilt in this case is due to the water-attracting group being attached in a position removed from the end of the

molecule, and to bring the molecules upright the hydroxyl group would have to be removed from the water.

The corresponding keto-compound, cholestane-6-one, occupies a much larger area at low compressions than the hydroxyl compound, and is much more compressible. Collapse at constant pressure occurs at about 16 dynes per cm. and 42 sq. Å. The larger area and compressibility of the keto-compound compared with the corresponding alcohol is a similar effect to that observed above with the 3-substituted compounds. Here the compressibility is much higher, however, and the value of  $\mu$ , unlike that of the 3-keto-compounds, falls as the compression rises. Models of this compound show that, tilted with the keto-group oriented nearly vertically, the compound would occupy about 60 sq. Å., and that tilting the molecule, still keeping the keto-group in contact with the surface, will allow this area to be reduced to approximately 50 sq. Å.; further reduction of area could only be obtained by partial removal of the keto-group from contact with the surface. This accounts qualitatively for the high compressibility of the film, and also for the fall in  $\mu$  which takes place on compression, since the keto-group is tilted to make a larger angle with the vertical.

$\Delta^4$ -Coprostene-7-ol (" $\psi$ -cholesterol") gives a surface pressure-area curve quite different from those of any of the hydroxy-compounds previously discussed. The area at 0.5 dyne per cm. pressure is about 80 sq. Å., and the film is extremely compressible; above 80 sq. Å. the curve falls off gradually to about 0.02 dyne per cm. at 120 sq. Å. Over this latter region, the fluctuations in  $\Delta V$  over the surface become much larger, of the order of 50 mv. In mixed films with cholesterol, the area of this compound was only slightly diminished, and the compressibility almost unaffected, indicating that, as with cholestane-6-ol, if the molecules are tilted, the tilt is not one which can be overcome by mechanical support from other molecules. The area under 0.5 dyne occupied by this coprostene-7-ol is dependent to some extent on temperature, being decreased by about 10 sq. Å. by a 15° fall of temperature, but there was no significant change in the form of the curve either on warming to 45° or cooling to 3°.

The cholestane ring system with the anchorage to the water at 7 must lie with the long axis of the molecule practically horizontal; the ring system may be on edge or flat. The side-chain may be stretched out flat or be perpendicular to the surface or be oscillating, as with the "expanded" films of aliphatic compounds. The models give an area for the flat ring-system with fully extended chain of about 130 sq. Å. We think it very unlikely, however, that many of the molecules are in this position even at the lowest pressures, since previous experience with many other types of molecules, some of which (e.g. apocholic acid below) would have more lateral adhesion when flat than  $\psi$ -cholesterol, shows that such molecules lying flat always give gaseous films; the film shows cohesion of a rather curious type, being heterogeneous according to the surface potential measurements above 80 sq. Å., but yet falling in surface pressure from 0.5 to 0.02 dyne between 80 and 120 sq. Å. We suggest that the films consist of aggregates of the ring systems adhering together, standing on edge with the long axis horizontal, and the chains oscillating in much the same way as they do in liquid expanded films. The cohesion is thus due to the adhering ring-systems, supplemented by the adhesion between the oscillating chains [v. Langmuir, 1933].

*Dihydroxy-compounds and their acetates.* Fig. 5 shows the data for the isomeric  $\alpha$ - and  $\beta$ -diols, whose structure [Rosenheim and Starling, 1933] is probably  $\Delta^5$ -cholestene-3:4-diol, the difference between the two compounds being probably due to one of the hydroxyls, most probably that in position 4, being normal in one isomeride and *epi* in the other.

$\alpha$ -Diol and its 3-acetate give identical surface pressure-area curves; the surface potential curves are similar, but that of the acetate is about 25 mv. higher. The film of  $\beta$ -diol occupies a larger area, is much more compressible and has a lower surface potential. Its 3:4-diacetate occupies a much larger area than the diol and has a considerably higher surface potential.

Fig. 5. Dihydroxy-compounds and their acetates. I.  $\Delta^5$ -Cholestene-3:4-diol ( $\alpha$ -diol). II. 3-Acetate of  $\alpha$ -diol. III.  $\Delta^5$ -Cholestene-3:4-diol ( $\beta$ -diol). IV. 3:4-Diacetate of  $\beta$ -diol.

Models show that, in order to bring both the hydroxyl groups to the lowest point of the molecule, different degrees of tilt are required with the four possible stereoisomerides of 3:4-diol. With the centres of the oxygen atoms in the same horizontal plane, the areas of the rectangles enclosing the tilted molecules are approximately as follows:

	Hydroxyl 3	Hydroxyl 4	Areas of tilted molecules (sq. Å.)
(a)	Normal	Normal	48.5
(b)	Normal	<i>Epi</i>	ca. 60
(c)	<i>Epi</i>	Normal	50.5
(d)	<i>Epi</i>	<i>Epi</i>	51

Configuration (a) is the smallest, (c) and (d) slightly larger, and (b) much larger, the tilt being larger, the greater the area given above—the area of all these models packed vertically being under 40 sq. Å. The observed areas are less than these, hence the molecules do not tilt to the extreme angle at which the centres of the oxygen atoms are in the same horizontal plane, but there is about the difference in area required on the supposition that the  $\alpha$ -diol has configuration (a) and the  $\beta$ -diol has (b). Further, the hydroxyl at 3 projects laterally if *epi* and continues the general line of the molecule if *normal*, so the fact that the 3-monoacetate of  $\alpha$ -diol has exactly the same area as the diol indicates that the 3-hydroxyl is normal. In the  $\beta$ -diol the *epi*hydroxyl at 4 projects sideways, so that the acetate occupies a considerably larger area than the diol. The surface pressure results agree with the configuration (a) for the  $\alpha$ -diol and (b) for the  $\beta$ -diol.

*Trihydroxy-compounds and their acetates.* Data for the following compounds are given in Fig. 6: cholestane-3:5:6-triol ("α-cholestanetriol"), cholestane-3:5:6-triol-3-acetate, cholestane-3:5:6-triol-3:6-diacetate and "β-ergostadienetriol".

The surface pressure-area curve for the parent cholestanetriol shows a limiting area for this substance of about 56 sq. Å. A rather smaller value for this substance was given by Adam and Rosenheim [1929]; the present value was obtained with three specimens spread from benzene solution (other, variable values were obtained if benzene-alcohol mixtures were used as the solvent; the reason for this is probably that the substance, having three hydroxyl groups, is near the limit of insolubility required by the surface pressure technique, and part of the solute tends to be carried below the surface when a solvent partially miscible with water is used. Using benzene as a solvent, there is little chance of this occurring, and the value given is probably correct).

Fig. 6. Trihydroxy-compounds and their acetates. I. Cholestane-3:5:6-triol. II. Cholestane-3:5:6-triol-3-acetate. III. Cholestane-3:5:6-triol-3:6-diacetate. IV. "β-Ergostadienetriol".

Measurement of a model of this compound shows that two of the hydroxyls, those on carbon atoms 3 and 6, can readily reach the water surface if the molecule is tilted to about  $45^\circ$  from the vertical, the main plane of the molecule remaining approximately at right angles to the surface; in this position the area occupied is approximately 52 sq. Å. To enable the third hydroxyl, that on carbon atom 5, to reach the water surface, the plane of the molecule must be tilted as well, the area then occupied being larger, about 66 sq. Å. The limiting area observed, 56 sq. Å., for the parent triol suggests that in this compound only the hydroxyls on 3 and 6 actually reach the surface. This is on the assumption that the hydroxyl on 6 is in the more favourable of the two possible positions, that in which it is approximately in the plane of the molecule; if it were in the alternative position, a much larger limiting area would be required. It is difficult to explain the very small surface potential shown by this compound; the possible explanation that might be advanced, that the hydroxyls are so arranged that their moments approximately cancel one another, does not appear to hold, since examination of a model shows that the resultant of the  $\text{—C—O—}$  linkages, at any rate, should have a moment of the same order of magnitude as that of one such

linkage; the explanation of this difficulty may lie in the unknown orientation of the hydroxyls round the  $\text{—C—O—}$  linkage.

The acetates of this triol, like the acetate of  $\beta$ -diol described above, give surface pressure curves having much larger limiting areas and compressibilities than the parent triol. Two factors probably contributing to this change are (a) the extra space taken up by the acetyl groups themselves, (b) the known weakening effect of acetylation on the water-attracting power of a hydroxyl group. In the monoacetate, which is acetylated in the 3-position, the weakening of the attraction of the 3-group for water may cause the molecule to tilt over to enable the 5-hydroxyl to reach the water; this would account for the limiting area observed, about 67 sq. Å. The diacetate, in which the 3:6-hydroxyls are acetylated, gives a film which is practically of the gaseous type, in which the molecule is probably lying flat on the surface. In these two acetylated compounds, the surface potentials and values of  $\mu$  are much larger than for the parent triol, a fact similar to that observed with the diacetate of  $\beta$ -diol. The value of  $\mu$  decreases considerably on compression, indicating that considerable tilt of the molecules takes place on compression.

The data for " $\beta$ -ergostadienetriol" are also given in Fig. 6. This is also considered to be a 3:5:6-triol [Rosenheim and King, 1934, 2; Windaus *et al.*, 1934]. The position here is complicated by the presence of the double bonds, but it does not appear, from the small value of the limiting area, that the molecule can be held in the surface by hydroxyls at 3 and 6. That the arrangement of the hydroxyls is different from that obtaining in cholestanetriol is also shown by the very much larger value of the surface potential. A possible, though admittedly very tentative, explanation would lie in the suggestion that whilst the compound is a 3:5:6-triol, the 6-hydroxyl is in the *epi*-position to that assumed in cholestanetriol. In this case it would, like the 5-hydroxyl, project sideways, but in the opposite direction. The fields of these two hydroxyls being thus to some extent opposed, the molecule would probably be more ready to assume positions in which only the 3-hydroxyl actually reaches the water. The value of  $\mu$  offers some support for this, in that it is of the same order as that of compounds containing a single hydroxyl orientated vertically.

**Diketones.** Two diketones of the cholestane series are shown in Fig. 7, cholestane-3:6-dione, and  $\Delta^4$ -cholestene-3:6-dione ("oxycholestenone").

Cholestane-3:6-dione (Fig. 7) shows a similar surface pressure curve to cholestane-6-one (Fig. 4), but the areas occupied are some 6 sq. Å. larger. In connection with the 6-keto-compound it was shown that the area and compressibility could be accounted for if the molecule tilts from a position in which the keto-group is nearly upright to one in which the molecule is as nearly upright as is consistent with the keto-group remaining attached to the water. Similar considerations hold in the case of the 3:6-diketo-compound, if we make the reasonable assumption that the second keto-group tends to keep the molecule rather more firmly attached to the surface, and since the 6-keto-group is tilted away from the vertical, as the 3-keto-group is tilted towards the vertical, we can account for the comparatively small change in  $\mu$ .

The corresponding unsaturated compound,  $\Delta^4$ -cholestene-3:6-dione gives rather similar surface pressure and surface potential curves, except in that they correspond to areas some 10 sq. Å. larger; the surface pressure curve of the cholestenedione is not unlike that of 7-substituted compounds, where the long axis of the molecule is lying extended along the surface. This behaviour of the unsaturated compared with the saturated ketone is to some extent parallel with that of the 3-keto-compounds (Fig. 2).

Fig. 7. Diketones. I. Cholestane-3:6-dione. II.  $\Delta^{15}$ -Cholestane-3:6-dione ("oxycholestenone").

Compounds with two or three different groups, at 3, 5, 6 or 7. Data for five compounds are shown in Fig. 8. Cholestane-3-ol-6-one gives a surface pressure curve, I, intermediate between that of cholestane-3-ol and cholestane-6-one. Its acetate, curve II, occupies a decidedly larger area, the molecules being more

Fig. 8. Compounds with two or more different water-attracting groups. I. Cholestane-3-ol-6-one. II. Cholestane-3-ol-6-one acetate. III. Cholestane-3:6-dione-5-ol. IV. Cholestane-3-ol-7-one acetate ("β-oxycholestenol acetate"). V. Cholestane-3-chloro-6-one.

tilted to the vertical. The tilt of the molecules is probably decided by the relative intensities of the attraction of the hydroxyl or acetate group at 3, and of the keto-group at 6, for the water. The attraction of the hydroxyl group is stronger than that of the keto-group, so that in the 3-ol-6-one compound the molecule is pulled rather more upright through the hydroxyl group becoming further immersed in the water than the keto-group. When the attraction of the

hydroxyl group for the water is weakened, though not destroyed, by acetylation, the two groups become more equally immersed in the water, tilting the molecule rather more.

Cholestane-3:6-dione-5-ol shows areas intermediate between those of the 3:6-dione and the 3:5:6-triol, the hydroxyl group pulling the molecule somewhat nearer the vertical position than with the 3:6-dione.  $\Delta^{5,6}$ -Cholestene-3-ol-7-one acetate (" $\beta$ -oxycholestenol acetate") is much less tilted than other compounds with a water-attracting group at 7, exerting practically no surface pressure at areas greater than 62 sq. Å. This result is difficult to reconcile with the constitution assigned on chemical grounds, but would be consistent with a constitution in which the keto-group was at 6.

Cholestane-3-chloro-6-one (from nitrocholesteryl chloride) occupies an area much greater than other compounds with a water-attracting group at 6. It is known [Adam, 1930, p. 84] that the chlorine in alkyl chlorides has very little attraction for water. Probably the molecule is anchored by the 6-keto-group alone, and possibly the size of the chlorine atom causes the area to be greater than that of the other compounds with one anchorage to the water at 6.

*The apocholic acids.* Fig. 9 shows the data for *apocholic* and  $\beta$ -*apocholic* acids, which crystallise with half a molecule of xylene: this probably evaporates when the films are spread. Both films are gaseous, and surface pressure and

Fig. 9. *Apocholic* acid and  $\beta$ -*apocholic* acid

surface potential are identical for the two isomerides, within experimental error. There are hydroxyl groups at 3 and 12 and a carboxyl at the end of the side-chain, in both acids: also one double bond which may be at 8-9 in *apocholic* [Wieland and Dane, 1932] but may be observed in the  $\beta$ -acid recently isolated by Callow (private communication). As usual, the three widely separated water-attracting groups cause the molecules to lie flat and the films are gaseous; similar gaseous films, with compounds containing the sterol skeleton and two or more water-attracting groups far apart in the molecule, have been previously found with oestriol, pregnandiol *etc.* [Adam *et al.*, 1932; Danielli *et al.*, 1933]. As the films are gaseous, with the molecules lying flat and relatively far apart, the small difference in the form of the molecules, if any, caused by the change in position of the double bond, does not produce any difference in the surface pressure curves of the two isomerides. The identity of the surface potential curves indicates that this isomerism does not involve any serious change in the orientation of the polar groups relatively to the ring system.

## SUMMARY.

Surface pressure and surface potential measurements of about 30 compounds related to the sterols are described. All the data are consistent with the modern view of the constitution of the sterol skeleton.

Most of the compounds show coherent condensed films.

Sterols with one hydroxyl at 3 and with not more than one double bond stand practically vertical in the surface; their area per molecule varies from 37 to 44 sq. Å., according to the stereochemical configurations of the ring systems. Highly unsaturated sterols are sometimes, but not always, tilted.

Ketones with one carbonyl at 3 tilt, sometimes far, from the vertical, but can be brought more nearly upright by admixture with sterols which normally stand upright in the surface.

One hydroxy- or keto-group at 6 or 7 causes the molecules to tilt considerably, in order that the group may come close to the water. This tilt is not altered by admixture with sterols standing upright. Keto-groups usually cause more tilt than hydroxy-groups. The molecules may tilt so that their long axis is practically horizontal, without the films losing coherence and becoming gaseous; the molecules may, however, be standing on edge, permitting much lateral adhesion between ring systems of adjacent molecules, in addition to that due to the hydrocarbon chains.

Compounds with two or three water-attracting groups in rings I and II always tilt. The amount of tilt depends on the position in the molecule and the relative attraction for water of the various groups.

Surface potential measurements sometimes indicate whether a hydroxyl group has the "normal" or the "epi" stereochemical configuration.

The apocholic acids form gaseous films with the molecules lying flat.

We are most deeply indebted to Drs Rosenheim and Callow for most of the material used, and to Prof. Ruzicka for the *epicoprosterol* and some other compounds. J. F. D. thanks the Surrey County Council and the Department of Scientific and Industrial Research for grants held during this work, and F. A. A. thanks the Medical Research Council for a grant.

# CCXI. THE VITAMIN B<sub>1</sub> CONTENT OF FOODS.

By AUDREY ZILLAH BAKER  
AND MARGARET DAVIDSON WRIGHT.

*From the Research Laboratory, Vitamins Limited, Hammersmith, London.*

*(Received May 31st, 1935.)*

It was shown by Drury *et al.* [1930] that on a diet deficient in vitamin B<sub>1</sub> young rats developed a progressive bradycardia which was cured by the administration of substances containing the vitamin but was unaffected by vitamins A, D, A and D combined and sources of vitamin B<sub>2</sub>. They also showed that the cure occurred without increased food intake and was therefore not secondary to the restoration of appetite. The bradycardia was sinus in origin and was not cured by the injection of barium or by vagal section.

This specific sign of vitamin B<sub>1</sub> deficiency has been further used by Birch and Harris [1934] for the quantitative determination of the vitamin B<sub>1</sub> in foods. Results obtained by this method were in line with assays made using other methods, *i.e.* the cure of convulsions in rats and the growth rate.

The bradycardia method has been compared in this laboratory with the growth-rate method of vitamin B<sub>1</sub> assay, and the findings of Birch and Harris that the method is reliable for quantitative determinations have been confirmed. The activity of samples of various substances determined by both methods is seen in Table I.

Table I.

Material	Units per g. (growth rate)	Units per g. (bradycardia)
Vitamin B <sub>1</sub> concentrate. 3310	97.0	115.0
Wheat germ (proprietary) sample M <sub>1</sub>	13.7	13.5
Wheat germ (proprietary) sample M <sub>2</sub>	14.0	13.75
Ox liver	1.4	1.5

Since there existed no comprehensive study of human foods in terms of the International Standard vitamin B<sub>1</sub>, and in view of the need for this in studying human requirements, it was decided to use the bradycardia method for assaying common foodstuffs, and with a view to the practical applications, to make the determination where possible on the food in the form in which it is normally eaten. Foods of low vitamin content have, of necessity, been assayed raw only.

The tests have been carried out during several months, throughout which period small groups of rats have from time to time been given graded doses of the International Standard. This has not only enabled a simultaneous assay to be made, but has also permitted a large number of standard readings to be collected (Table II).

Between the dose levels of 20 and 30 mg., the method gives an accuracy within  $\pm 20\%$ . The probable error at the level of 30 mg. is  $\pm 17\%$  when all values are considered, but is reduced to  $\pm 14\%$  when the four extreme values (out of 28) are omitted. It has therefore been attempted to give doses calculated to produce a cure of about 3 days' duration but, owing to the small traces of the vitamin in many foods, this has not always been possible. Considerations

Table II. *Duration of cure obtained with International Standard.*

10 mg. Hours	15 mg. Days	20 mg. Days	30 mg. Days		40 mg. Days	50 mg. Days

of time have not so far permitted the use of several dose levels for each food but these are gradually being worked out, as also are the seasonal foods not included in Table IV.

#### PROCEDURE.

Rats of 130–140 g. wt. and of either sex are kept on a diet consisting of:

Castor sugar	...	...	...	60	100 parts.
Arachis oil	...	...	...	15	
"Light white casein"	...	...	...	20	
McCollum's salt mixture	...	...	...	5	
Autoclaved dried brewer's yeast 15 % of basal diet <sup>1</sup> .					
Cod-liver oil, one drop daily per rat.					

The rats are housed 3 or 4 in a cage on screens, in rooms kept at 65° F. by a thermostatically controlled heating system. They are fed twice daily to minimise errors arising from wastage and subsequent lack of food. After about 4 weeks, the depleting rats are put into single cages (8 × 8 × 10 in.) with  $\frac{1}{2}$  in. mesh floors, standing 2 in. above deep trays, and daily readings are taken on the Matthews electrocardiograph. Readings are usually begun when the body weight is about 110–125 g. By using depleted rats at this weight, each animal can be used for 8 or more tests before its usefulness is ended by convulsions, severe inanition or a premortal fall of temperature. Fig. 1 shows a typical series of responses for one animal, compared with progressive bradycardia of a negative control.

Readings, except in the case of low levels of standard, have been taken once in 24 hours, but a definite sequence has been followed and each animal examined at approximately the same hour each day. Those suitable for use have received a test dose as soon as their heart rate is known. In attempting to give doses

<sup>1</sup> Autoclaved for 6 hours at 120° in layers 1 in. deep.

During the early part of this work a number of rats developed ulcers and oedema of the feet and tail, loss of hair and staining of the abdominal fur. As a result of this the autoclaved yeast, which had been used as 10 % of the diet, was increased to 15 % and the subsequent disappearance of the lesions led to the conclusion that the diet as originally used had been inadequate in vitamin B<sub>4</sub>. The alteration was without effect on the heart-rate records.

which would produce an approximate 3-day cure, the large amounts required in many cases have so far deterred us from testing at a second and higher level. Doses of 2 or 4 g. have been used for most foods, and occasionally 6 g. in two equal parts at 6-8 hours' interval. Bulky materials have been chopped or ground and observation made to prevent wastage of dose.

Fig. 1.

Most foods have been given when the heart-rate is between 350 and 450 per minute, and tests of each substance have been made at both the higher and lower rates. Between these limits duration of the response does not depend upon the initial heart rate (see Table III).

Table III. *Relation between initial heart rate and duration of response.*

Material	Initial heart rate	Duration of response Days	Material	Initial heart rate	Duration of response Days
Egg yolk	430	3.0	Mushroom ( <i>cont.</i> )	390	2.5
	420	2.6		374	1.2
	420	2.8		354	2.1
	354	3.75	Grape fruit	450	1.5
	340	2.45		420	2.3
Mushroom	462	2.1		400	1.2
	450	2.1		370	1.8

When rats with heart rates above 450 have been used, many of the responses have tended to be prolonged or irregular. This applies particularly to the first dose given after the depletion period and is shown in Fig. 2 which illustrates an abnormal initial response followed by eight normal responses.

After the first dose the rhythm of response appears to become established and further abnormalities are unusual until the final or penultimate test. Abnormal responses have occurred to 40% of the initial doses given to 130 rats and have led us to adopt the practice of giving, when the heart rate is between 440 and 460, a preliminary dose of 300 mg. wheat germ (proprietary), not to be considered for assay purposes, and beginning the routine tests when the heart rate is falling daily after the maximum response. Certain other atypical readings have been discarded. Most of these are from the last dose given, when

the rat has been well enough to take the dose, and has succumbed to, or been chloroformed for, rapidly developing inanition before the response was completed. Disregarding the initial steadying dose which is no longer given for purposes of assay, the discarded responses amount to 10.7 % of 1200.

Fig. 2. Initial abnormal response followed by eight normal responses.

It will be seen in Table IV that the substances showing a high probable error have given in most cases one or more negative responses. Some of these may be due to the test substance not being homogeneous, as in sardine, but in other instances no such explanation suggests itself. A negative response has been included in the table only when examination of the previous and subsequent history of the animal concerned has shown it to give normal responses to other substances.

Table IV.

\* indicates that the probable error for the dose used is over 50%.

With regard to substances of high vitamin B<sub>1</sub> activity, such as yeast and wheat germ, the variation from sample to sample is considerable. Thus with brewer's yeast some samples have been found four times as active as others. Quinn *et al.* [1930] record a 10-fold variation in yeasts. On several hundred samples of wheat germ drawn from a large number of sources, and examined here, a 5-fold variation has been found. Comparable variations probably occur in other cereal germs, of which we have been able to examine only a small number.

## SUMMARY.

1. The reliability of the cure of bradycardia as a means of estimating the vitamin B<sub>1</sub> content of various substances has been confirmed.
2. This method has been used for the estimation, in International Units, of the vitamin B<sub>1</sub> content of a number of foods.

We wish to express our thanks to Dr Leslie Harris and his department at the Dunn Nutritional Laboratories for valuable instruction in technique, to Prof. J. C. Drummond for helpful criticism, and to the Directors of Vitamins, Limited, for the facilities they have given to make this work possible.

## CCXII. ENZYMES IN CANCER. THE $\beta$ -GLYCERO-PHOSPHATASE OF THE ERYTHROCYTES.

By JANETTA WRIGHT SCHOONOVER AND JACOB OWEN ELY.

*From the Cancer Research Laboratories, Graduate School of Medicine, University of Pennsylvania, and the Radiological Clinic of the Philadelphia General Hospital, Philadelphia, Pennsylvania.*

(Received May 10th, 1935.)

A PHOSPHATASE with an optimum  $p_H$  of about 9 has been found in practically every tissue. Kay [1932] presented conclusive evidence for the identity of the alkaline phosphoesterases of the bone, kidney, intestinal mucosa and blood plasma. Lesions of the bone, kidney, liver *etc.*, or hyperactivity of various organs augment the activity of the plasma enzyme [Kay, 1930, 2; Bodansky, 1934]. To such mechanical reasons must be attributed the slight increase of  $\beta$ -glycerophosphatase observed in cancer plasma by Kay [1930, 2], and in cancer whole blood at  $p_H$  8.8 by Köhler [1934].

There are two acid phosphatases, which are not identical in spite of their similar  $p_H$  optima. One is found in the red blood cells; it hydrolyses  $\beta$ -glycerophosphate most effectively at  $p_H$  6.0-6.2 [Roche, 1931]. The other is contained in, at least, liver, kidney and spleen. Davies [1934] assigns to it an optimum  $p_H$  of 5.0, Bamann and Riedel [1934] assign one of 5.5. The erythrocyte enzyme is activated by magnesium ions at its optimum  $p_H$  [Davies, 1934]; the organ enzyme is not [Davies, 1934; Bamann and Riedel, 1934]. The erythrocyte phosphatase in cancer has not been studied, so far as can be ascertained.

Köhler [1934] observed that blood phosphatase of cancerous rats, at  $p_H$  8.8, displayed less proportionate increased activity than did that of normal rat blood, at the same  $p_H$ , when magnesium chloride was added. In view of the fact that the plasma and the erythrocytes contain different phosphatases, this variation in behaviour might be due to either or to both. Both phosphatases are capable of activation by magnesium at  $p_H$  7.6 [Kay, 1930, 1; Jenner and Kay, 1931], and presumably would be affected at  $p_H$  8.8 also. Therefore, it seemed necessary to conduct separate investigations of the effect of the magnesium ion on plasma phosphatase and on erythrocyte phosphatase.

Plasma was the first selection for study. Bodansky's [1933] method for the determination of serum  $\beta$ -glycerophosphatase was employed as a basis. It was modified to permit the estimation of the plasma enzyme at  $p_H$  8.8-9.17<sup>1</sup>, with and without the addition of magnesium chloride in the reaction mixture in concentrations varying from 0.001 to 0.05 *M*. No significant differences were found between normal plasma and cancer plasma. Indeed, both types frequently showed no activation at all at  $p_H$  8.8.

The red blood cells, then, remained as the only possible source of the differing response of normal blood phosphatase and of cancer blood phosphatase to magnesium chloride. Although Köhler's [1934] results were obtained at  $p_H$  8.8, the

<sup>1</sup> This was the highest  $p_H$  obtainable without substituting sodium hydroxide for hydrochloric acid in the veronal buffer. With the use of sodium hydroxide, optima were always observed at  $p_H$  9.2-9.3, but it was not possible to study the effect of the magnesium ion at these values because of the precipitate formed when magnesium chloride was added to the buffered substrate.

region of the optimum  $p_H$  of the red cell enzyme was the one chosen for study. This was done with the belief that differences occurring at  $p_H$  8.8 would also be found at the optimum if they were of physiological significance.

The results have justified this belief. The red cell enzymes from normal and cancerous human blood have been studied over the substrate  $p_H$  range of 5.0-6.0, whereby the optimum for both types was found to be 5.6-5.8. Cancer  $\beta$ -glycerophosphatase was found to be the more active over the entire range if the results are segregated according to sex. Both cancer and normal erythrocytes from the same sex exhibited the same unit increase in the presence of equivalent amounts of added magnesium chloride. Consequently the increase % was lower in the cancer cases. It is believed that these results indicate the presence of some of the organ phosphatase in cancer erythrocytes.

#### EXPERIMENTAL.

It was found that 0.1 ml. of erythrocytes was sufficient for each determination, thus making it possible to study one sample over a wide range of  $p_H$  values and magnesium concentrations. Acetate buffer, 0.2  $M$  in the reaction mixture, was employed and found satisfactory, although we have no evidence of its producing any specific stimulating or depressing effect on the enzyme.

The  $p_H$ -elevating effect of sodium  $\beta$ -glycerophosphate on the buffer, noted by Davies [1934] and by Bamann and Riedel [1934], was observed. In addition, magnesium chloride was found to exert a reverse influence on the buffered substrate; this influence was directed towards the glycerophosphate and was not overcome by the presence of the buffer. For these reasons, it was necessary to compile a series of data, using the quinhydrone electrode at room temperature, for the preparation of buffered substrates of varying  $p_H$ ; the proportions of the components differed according to the molarity of the magnesium chloride to be present in the reaction mixture. The quantities given in Table I show the requisite amounts of 1.25 % Na  $\beta$ -glycerophosphate (Eastman Kodak) 0.5  $M$  in acetic acid and of 1.25 % Na  $\beta$ -glycerophosphate 0.5  $M$  in Na acetate (both solutions were made up fresh daily) to prepare 4 ml. of buffered substrate. This quantity is increased by the addition of 1 ml. of water if no magnesium chloride is to be added, by the addition of 1 ml. of 0.2  $M$  magnesium chloride if the reaction mixture is to be 0.02  $M$  in added magnesium chloride *etc.*

Table I. *Preparation of buffered substrates for use with various molarities of magnesium chloride in the reaction mixtures.*

6.0	0.41	3.59	0.27	3.73	0.21	3.79	0.11	3.89

The preparation of a buffered substrate of  $p_H$  6.0 for use in a reaction mixture 0.02  $M$  in  $MgCl_2$  requires the following proportions: HOAc, 0.34 ml.; NaOAc, 3.66 m

*Method of estimation.* One volume of unwashed erythrocytes was laked with 4 volumes of water. After 15 minutes, 5–10 ml. of the laked cells were withdrawn for the inorganic phosphorus determination. Sufficient water was added to the remainder to make the final dilution 1:50. 5 ml. of this haemolysate, containing 0.1 ml. of erythrocytes, were added to 5 ml. of buffered substrate in an 18 × 150 mm. test-tube, 4 drops of chloroform added and the tube was closed with a clean No. 2 rubber stopper, inverted once and placed in the water-bath. This procedure took half a minute, so that 30 reactions could be started in 15 minutes. After 24 hours in the water-bath at  $37 \pm 0.1^\circ$ , the tube was removed and placed in ice water. Two minutes later, 10 ml. of 9% trichloroacetic acid were added, the tube was closed with a rubber stopper and shaken 20 times in an inverted position to facilitate the breaking up of the precipitate which always formed and settled to the bottom of the tube during the incubation. The mixture was filtered through Whatman No. 44 filter-paper 10 minutes later. The inorganic phosphorus in these filtrates was determined according to the modification of the procedure of Kuttner and Cohen [1927] outlined by Bodansky [1932] in his serum inorganic phosphate method. Calculation of the number of mg. of inorganic phosphorus present in the filtrate aliquots (the size of the aliquot was carefully chosen to give a colorimetric reading of as near 20 mm. as possible) was made by using Bodansky's [1932] table for the effect of Beer's law and his factors for the influence of  $\beta$ -glycerophosphate and trichloroacetic acid on the colorimetric reading<sup>1</sup>. The calculation of the inorganic phosphorus present in the red cell haemolysate was also made with the use of the Bodansky table and factors. Both of these figures were finally referred to 10 ml. of erythrocytes. The amount of inorganic phosphorus originally present, although negligible, was subtracted from the amount found after the action of the enzyme on the glycerophosphate, and the result was the number of mg. of inorganic phosphorus freed from the ester in 24 hours. For the purposes of this report, therefore, a unit of erythrocyte phosphatase is defined as that quantity, existing in 10 ml. of red blood cells, which will liberate 1 mg. of inorganic phosphorus in 24 hours at  $37^\circ$  in 0.2 *M* acetate buffer.

By this method, the substrate optimum for normal and cancerous human  $\beta$ -glycerophosphatase action was established at  $p_H$  5.6–5.8.  $p_H$ -activity curves for 4 normal males and 6 cancer patients will be found in Fig. 1; they illustrate the choice of the 5.6–5.8 optimum.

Preliminary studies indicated that the highest activation of both normal and cancer erythrocyte phosphatase at substrate  $p_H$  5.6 occurred with the use of 0.05 and 0.075 *M* magnesium chloride. Therefore, simultaneous studies were made on the same sample, over the range  $p_H$  5.0–6.0, in reaction mixtures 0, 0.05, 0.075 and 0.10 *M* in added magnesium chloride. The results of these studies were averaged and are found in Figs. 2 and 3. From these it is seen that there is a tendency for magnesium in increasing concentration to produce

<sup>1</sup> Since the amount of glycerophosphate originally present in the reaction mixture was the same as that used in the Bodansky [1933] method, and since Bodansky made no allowances for varying amounts being used up during the reaction, it seemed fair to assume that the influence of the ester could be rectified in this way. Less justifiable, perhaps, was the assumption that the concentration of trichloroacetic acid in a filtrate from 20 ml. of 4.5% trichloroacetic acid containing 0.1 ml. of erythrocytes would exert the same influence on the colorimetric reading as would the concentration of trichloroacetic acid in a filtrate from 20 ml. of 4.5% trichloroacetic acid containing 1.0 ml. of serum. However, duplicate readings with different quantities of the same filtrate gave results agreeing within  $\pm 5\%$ , which showed that this assumption was well grounded.

Fig. 3.  $p_{\text{H}}$ -activity curves for the  $\beta$ -glycerophosphatase of the erythrocytes of five cancer patients of both sexes (A) without the addition of  $\text{MgCl}_2$  to the reaction mixture, (B) with  $0.05M$   $\text{MgCl}_2$ , (C) with  $0.075M$   $\text{MgCl}_2$ , and (D) with  $0.10M$   $\text{MgCl}_2$  added to the reaction mixture.

its maximum effect as the  $p_H$  becomes lower: this effect is more pronounced in the instance of the normal males (Fig. 2).

The work was therefore continued in a simplified form. The erythrocyte phosphatase of normal females and of cancerous individuals was studied at  $p_H$  5.0, 5.6 and 6.0, without the addition of magnesium chloride and also with the addition of 0.10, 0.05 and 0.02  $M$  magnesium chloride respectively. From these series it was found that the unit increase varied from individual to individual, but that the ranges and averages were very similar for all females at each  $p_H$  and for normal males and untreated male cancer patients at  $p_H$  5.6. The figures will be found in Table II. This table also contains data obtained in the preceding series.

	<b>Average</b>	<b>19.3</b>	<b>13.1</b>	<b>17.7</b>	<b>15.0</b>	<b>19.2</b>	

The percentage increase, for this reason, is not the same in normal and cancer erythrocytes from individuals of the same sex. The red blood cells of cancer patients, and particularly of those who had received radiation therapy, exhibited a higher  $\beta$ -glycerophosphatase activity at the  $p_H$  values studied than did the red blood cells of normal subjects (this was noticeable in Fig. 1). Hence, less percentage activation was obtained in cancer erythrocytes by the addition of magnesium chloride than was found in normal erythrocytes. The difference was not marked at  $p_H$  6.0 with 0.02  $M$  magnesium chloride, but much more so at  $p_H$  5.6 with 0.05  $M$  magnesium chloride, and was considerably exaggerated at  $p_H$  5.0 with 0.10  $M$  magnesium chloride. The results (including those obtained in the preceding series) have been averaged and are presented in Figs. 4 and 5, with the units of phosphatase found without addition of magnesium expressed by points on the left-hand scale, and the percentage increase found with the stated molarity of magnesium chloride added to the reaction

mixture by the points on the right. Lines have been drawn connecting the pairs of points for each type of subject, the slopes of which depict the results just described.

Fig. 4. Units of erythrocyte  $\beta$ -glycerophosphatase from male subjects without addition of  $\text{MgCl}_2$  to reaction mixture (left-hand scale) and percentage increase with addition of stated molarity of  $\text{MgCl}_2$  (right-hand scale). — connect pairs of points representing averages obtained from four normals; --- those for six untreated cancer patients; . . . those for three cancer patients treated by irradiation.

Fig. 5. Units of erythrocyte  $\beta$ -glycerophosphatase from female subjects without addition of  $\text{MgCl}_2$  to reaction mixture (left-hand scale) and percentage increase with addition of stated molarity of  $\text{MgCl}_2$  (right-hand scale). — connect pairs of points representing averages obtained from five normals; --- those for three untreated cancer patients; . . . those for three cancer patients treated by irradiation.

## DISCUSSION.

Whilst actual  $p_{\text{H}}$  measurements were not made in the reaction mixture itself, it is a fair assumption that the  $p_{\text{H}}$  of 10 ml. of 0.2  $M$  acetate buffer, containing 0.5 % sodium  $\beta$ -glycerophosphate, is not appreciably altered by the inclusion of 0.1 ml. of erythrocytes. The establishment of the optimum substrate  $p_{\text{H}}$  for human (unwashed) erythrocyte  $\beta$ -glycerophosphatase activity at 5.6–5.8 is no contradiction of any previously published data available to us. The other optima reported refer to animal erythrocytes, which, according to Roche [1931] and Roche and Latreille [1934], may show species variation. Moreover, the degree of purity may be a controlling factor, as Bamann and Riedel [1934] have pointed out with regard to organ autolysates.

It is granted that the enzyme solutions employed in this study were very crude, but, since it was desired to study the difference between the activity of normal and cancer enzymes in their natural state, purification processes of any sort were avoided for fear of removing some activating substance. In this way, we worked with conditions comparable with those of Davies [1934] for spleen

extracts, and with those of Bamann and Riedel [1934] for undialysed organ autolysates.

There is no evidence that the "acid phosphatases" of these two sets of authors are not the same. That is, their phosphatases display  $p_H$  optima near to each other, and the behaviours of the two are alike in that magnesium chloride (0.006  $M$  in Davies's experiments and unstated in Bamann and Riedel's) produces a slight inhibition below the optimum  $p_H$  and only begins to activate when this  $p_H$  is exceeded. These studies were published when our work was nearly completed, but the discovery that less magnesium chloride was needed for activation as the  $p_H$  becomes more alkaline hints that a concentration well below 0.05  $M$ , the lowest we used over the entire range  $p_H$  5.0–6.0, might be discovered which would not activate at all at the lower  $p_H$  values. However, any theory regarding the identity of the acid phosphoesterase of the organs and that of the erythrocytes is refuted by two facts. Davies demonstrated that  $\beta$ -glycerophosphate was hydrolysed three times as fast as the  $\alpha$ -ester by spleen extracts, whilst he was able to confirm Roche's [1931] statement that the reverse is the case when these two substrates are presented to the dephosphorylating enzyme of the erythrocytes. Bamann and Riedel were unable to produce any activation of the  $\beta$ -glycerophosphatase from dialysed organ autolysates at  $p_H$  4.0, 5.0 and 6.0 with magnesium chloride in concentrations up to 0.05  $M$ . We found considerable activation of human erythrocyte  $\beta$ -glycerophosphatase at  $p_H$  5.0–6.0 with 0.05  $M$  magnesium chloride.

If, however, there is a real difference in the response to the magnesium ion between these two acid phosphatases, the organ and the erythrocyte, the difference between the dephosphorylating powers of cancer and of normal red blood cells with and without the artificial addition of magnesium chloride could be explained on that basis. It will be recalled that the erythrocytes of cancer patients were found to exhibit a greater initial phosphatase activity at all  $p_H$  values studied in the range 5.0–6.0 than did erythrocytes from normal individuals of the same sex. When the magnesium concentration of the reaction mixture was increased, the units of phosphatase were augmented, in general, by the same absolute amount in both normal and cancerous persons of the same sex. Variations in original magnesium concentration could account for this behaviour only if one assumed that the magnesium exists in some special complex in the body. However, a more logical explanation is that the increase in erythrocyte  $\beta$ -glycerophosphatase activity in cancer is due to the presence of some of the organ phosphoesterase, or to more of it than exists in normal erythrocytes, thereby increasing the apparent activity of the red cell enzyme. The addition of magnesium activates the true erythrocyte phosphatase but leaves the organ phosphatase unaffected.

If such is the case, one would expect to find the ratio of the rates of hydrolysis of  $\alpha$ -glycerophosphate and  $\beta$ -glycerophosphate by cancer erythrocytes to be less than a similar ratio for normal erythrocytes. This theory is being investigated.

#### SUMMARY.

The optimum substrate  $p_H$  for normal and cancer human erythrocyte  $\beta$ -glycerophosphatase activity, in 0.2  $M$  acetate buffer at 37°, has been shown to be 5.6–5.8. Cancer erythrocytes have been found to exhibit, in general, a higher phosphatase activity than do erythrocytes from normal subjects of the same sex over the  $p_H$  range 5.0–6.0. The unit increase with selected artificial elevations of the magnesium ion concentration in the reaction mixture has been

found to be the same in both normal and cancerous individuals of the same sex. The significance of these findings is discussed.

We wish to express our gratitude to Dr Ellice McDonald for his advice and for his interest in this work. We are indebted to the division of pathology of the laboratories of the Philadelphia General Hospital for the histological diagnoses of all the cancer cases studied in connection with this investigation.

## CCXIII. THE CHEMISTRY OF HEPARIN.

BY ERIK JORPES.

*From the Physiological Chemistry Department of the Caroline Institute, Stockholm,  
and the Insulin Laboratory of the Vitrum Company, Stockholm.*

*(Received May 13th, 1935.)*

HEPARIN, the anticoagulant discovered by Howell [1918], has not until recent times been readily accessible either to the research chemist or to the physiologist. Its high price has prevented a thorough study of its chemical properties and its more extensive use in physiological laboratories and in clinical practice. Thanks to the recent work of Charles and Scott [1933], fresh possibilities have been afforded in both directions. Heparin has been shown to be a common tissue constituent, and the method of its preparation has been greatly improved.

As to the chemical nature of heparin, very little is known. Howell [1928] found a hexuronic acid in his purest preparations. Schmitz and Fischer [1933] described highly purified preparations, which they believed to consist of a trisaccharide,  $C_{18}H_{32}O_{17}$ , containing one carboxylic group. Charles and Scott found a positive  $\alpha$ -naphthol reaction, but the test for hexuronic acids with naphthoresoreinol was negative. Consequently the authors agree only in one respect, namely as to the occurrence of carbohydrate groups in the heparin preparations. Furthermore, there is disagreement as to the nitrogen content of the preparations. Howell found at an early stage of the preparation that the sodium cyanide test of Lassaigne proved negative, and he gives no further information as to the nitrogen content. Nor do Schmitz and Fischer pay any attention to this question. On the contrary Charles and Scott found about 2% of nitrogen in their purest preparations, which were as pure as any hitherto prepared. Another finding in the papers of these investigators is also remarkable, namely the high ash content of the heparin samples. Howell found 37 % and Charles and Scott about the same figure. Schmitz and Fischer, who found a certain amount of ash even in the crystalline brucine salt, repeatedly discuss the possibility of molecular combination between heparin and neutral salts.

This divergence of opinion as to the composition of heparin preparations seemed to justify a reinvestigation. The author therefore prepared heparin from ox and horse liver, following the principles outlined by Charles and Scott. Only in some details was their technique modified. The crude material obtained after tryptic digestion proved to be 2 or 3 times more active than the commercial preparations. After treatment with Lloyd's reagent 2 or 3 times as recommended by Howell, no considerable further purification seemed possible. Several attempts to fractionate the preparations with barium acetate, barium hydroxide, lead acetate (basic) and glacial acetic acid did not result in more active products. In this state of purity the samples did not precipitate in aqueous solution with lead acetate or with cadmium chloride. As further purification seemed impossible, the samples were submitted to analysis.

### *Analysis of the heparin preparations.*

The different preparations of heparin seemed to be of a rather uniform chemical composition (see Tables I and II). Furthermore the content of ash, 38–41 %, and of nitrogen, 1.63–1.84 %, corresponded with the figures given by Charles and Scott.

As Howell's statements as to the occurrence of a hexuronic acid seemed to be quite convincing, the samples were submitted to a quantitative analysis for uronic acids according to Tollens-Lefèvre. The micromethod of Dickson *et al.* [1930] was applied and somewhat modified by the author. The carbon dioxide evolved corresponded to a content of hexuronic acid of 17–19% calculated on air-dry substance. If the high ash content is taken into account, the content of uronic acid found is quite considerable.

The presence of a hexosamine was also detected and an estimation by the method of Elson and Morgan [1933] showed between 12 and 14%, calculated on air-dry substance. As these two constituents, hexuronic acid and hexosamine, are characteristic for chondroitinsulphuric acid, a test was made for ester sulphates. It proved to be positive. Furthermore, a certain amount of acetic acid was found on analysing for *N*-acetyl. Thus the samples seemed to contain chondroitinsulphuric acid, and to such an extent that there was hardly room for any other active organic component (see Table II). The chondroitinsulphuric acid however proved to be completely devoid of anticoagulating activity.

		95.51	91.73	96.91	93.94	95.39	—

The ash was proved to consist of magnesium sulphate. As to its origin, it is evident that the magnesium originates from the Lloyd's reagent. A certain amount of sulphate could also be extracted with water from the adsorbent and precipitated by 1.5 vols. acetone. This amount however was not nearly sufficient

to explain the high ash content of the heparin samples, particularly as it was found that only a small amount of sulphur could be precipitated with barium chloride. Furthermore, some samples were reprecipitated 3 times by 1.5 vols. acetone. The heparin samples showed a sulphur content of about 11 %, calculated on air-dry substance. Only 3.5–4 % was precipitated directly with barium chloride in slightly acidic solution. The remainder, about 7.5 %, could be precipitated only after acid hydrolysis (see Table III).

In view of this high content of ester sulphates particular attention was paid to the possibility that the chondroitinsulphuric acid might prevent the precipitation of the barium sulphate. The free sulphates were first precipitated with barium chloride in 0.1N HCl solution. After  $\frac{1}{2}$ –1 hour the precipitate was collected in a Neubauer-Gooch microcrucible. Then the solution was left standing for 24 hours at room temperature, without any formation of a new precipitate. On adding a definite amount of sodium sulphate (corresponding to 27.2 mg.  $\text{BaSO}_4$ ), a precipitate immediately formed, which was collected after an hour, about the theoretical amount of  $\text{BaSO}_4$  (28.2 mg.) being recovered. The same experiment was repeated several times with the same result. When the solution was boiled, however, a precipitate formed which for two samples agreed well with the total amount of ester sulphates.

Further and definite proof of the correctness of this analysis was obtained by means of dialysis in a collodion sac and electro-dialysis through a parchment membrane. In both cases only the free sulphates were found in the outer and anode liquor, and about the theoretical amount of ester sulphates in the inner liquor.

Seeing that 7.5 % sulphur requires about 28 % ash, calculated as magnesium sulphate, the high ash content of the heparin preparations of previous investigators apparently originates from the ester sulphates. In a sample with 11 % S the corresponding figure is 42 %. The ash content of the author's heparin preparations agreed well with this figure. There was also a striking correspondence in the ash content of the purest heparin preparations referred to later with the figures calculated for the ash from the S content.

Calc. for 3 atoms S per mol. chondroitin			8.55	9.39	8.91	8.78	—

As is evident from Table II, the samples analysed here consisted of chondroitin and ash almost exclusively. The fairly accurate Tollens-Lefèvre method allows such a conclusion to be drawn, particularly as the hexosamine content was almost theoretical and acetic acid was found to be present. This being the case, it will be necessary to assign the ester sulphates to the chondroitin, where

already about 3 % sulphur is fixed as chondroitinsulphuric acid. Consequently the question of a chondroitinpolysulphuric acid must be considered.

The content of ester sulphates in the purified heparin preparations is given in Table III. The figures are to be considered somewhat uncertain, since there is no proof of the quantitative recovery of the free sulphates. Repeated analyses gave figures slightly deviating from those given in the table, although without impairing the results. The amount of ester sulphates corresponded to about 2.5 atoms of S per mol. of chondroitin. Seeing that, both in the hexosamine and in the hexuronic acid, there are three hydroxyl groups available for esterification, a tri- or di-sulphuric acid would be the most likely to occur. Levene [1925] tentatively assigns the sulphur group of the chondroitinsulphuric acid to  $C_6$  of the hexosamine. 2.5 atoms of S per mol. of chondroitin would require that one of the sulphate radicals combines with 2 mols. of chondroitin. A more plausible explanation would therefore be that the samples contain a mixture of different chondroitinsulphuric acids. In spite of the similarity in the chemical properties of these acids it was possible by means of alkaloids to separate a fraction having the composition of a chondroitintrisulphuric acid and showing an increased heparin activity, whereas the chondroitinsulphuric acid isolated from the mother liquor showed a lower sulphur content.

*The properties of the purified heparin preparations.*

The preparations of heparin analysed showed the properties described by the previous investigators. No precipitate was obtained with metal salts, except with basic lead acetate, which also precipitates chondroitinsulphuric acid.

For the study of the solubility of the different salts of heparin and of chondroitinsulphuric acid they were electrodyalysed with a parchment membrane to almost neutral reaction of the cathode liquor. The free acids were then neutralised in small portions with alkaline solutions of the different metals.

The free acids are soluble in an excess of methyl alcohol, ethyl alcohol, acetone and glacial acetic acid. The sodium, potassium and ammonium salts, when dissolved in several volumes of these liquids only flocculate after addition of a certain amount of foreign electrolytes. A solution of the calcium salt shows no opalescence on the addition of 1 vol. of methyl alcohol, slight opalescence with 1 vol. of ethyl alcohol and flocculates with 1.5 vols. of acetone. The barium salts are readily precipitated in these conditions. The magnesium salt needs for its precipitation the addition of some sodium chloride, which is extensively used in the preparation and purification of heparin.

These properties are common to heparin and chondroitinsulphuric acid, as is the precipitability of their salts by means of glacial acetic acid and basic lead acetate. In one respect, however, there is a difference. Heparin flocculates on the addition of an excess of barium hydroxide whereas chondroitinsulphuric acid remains in solution. This property however has been proved by the previous investigators to be of little or no value in the purification of heparin.

A noteworthy difference was found in their behaviour towards alkaloids, particularly in the solubility of their brucine salts. The electrodyalysed solutions were neutralised with solutions of the alkaloid bases in methyl alcohol. Morphine and cinchonine gave no precipitate. With quinine, both heparin and chondroitinsulphuric acid flocculated in the cold, but with brucine only the heparin precipitated. After removal of the brucine from this precipitate a preparation was obtained showing a content of hexuronic acid, hexosamine and ester sulphates calculated for a chondroitintrisulphuric acid.

*The separation of a chondroitintrisulphuric acid from the purified heparin preparations by means of alkaloids.*

On adding morphine, cinchonine, brucine and quinine, or their salts to a neutral solution of heparin, a precipitate was obtained only with quinine and its hydrochloride. When the precipitate was collected and the base was removed with sodium hydroxide and chloroform, and the heparin precipitated with acetone in the usual way, the content of ester sulphates proved to be considerably higher than in the initial material. It corresponded well with the calculated content for a chondroitintrisulphuric acid.

Seeing that chondroitinsulphuric acid also gives a sparingly soluble quinine salt on cooling and freezing the solution, the precipitate obtained with quinine must be considered as less specific. Brucine proved more useful, for the pure brucine salt of heparin is insoluble in water, whereas chondroitinsulphuric acid does not give any precipitate with brucine under the same conditions. A brucine salt of heparin stated to be crystalline was also prepared by Schmitz and Fischer.

In order to obtain the pure brucine salt, the positive ions of the heparin samples, as well as the free sulphates were removed by electrodialysis. When the strongly acid solution of the inner cell was neutralised with brucine dissolved in methyl alcohol, only a slight opalescence appeared. When the solution was kept in the cold and frozen 2 or 3 times during the course of a week a considerable amount of precipitate separated. The brucine salt settled out in spherical masses much like crystals of crude leucine, without any other visible particles in the microscopic field. On boiling with sufficient water, the precipitate dissolved and could be purified by repeating this procedure.

As no certain conclusion can be drawn from the analysis of the brucine salt, the precipitate and the mother-liquor were analysed after removal of the brucine.

The material recovered from the insoluble brucine salt again showed a content of about 20% of uronic acid and a sulphur content corresponding within 3-4% to the calculated figures for a chondroitintrisulphuric acid. The hexosamine content, determined with the Ehrlich reagent as recommended by Elson and Morgan also agreed with the theoretical figure.

The substance recovered from the mother-liquor after removal of the insoluble brucine salt showed about the same or a slightly higher content of uronic acid and hexosamine, and a sulphur content somewhat lower than would be the case in a chondroitindisulphuric acid.

The use of brucine in isolating the trisulphuric acid is thus very valuable. If the same experiment is repeated with electrodialysed chondroitinsulphuric acid, only a trace of brucine salt settles out when the solution is frozen. The substance recovered from this precipitate in one experiment was only 2.4% of the amount of chondroitinsulphuric acid recovered from the mother-liquor.

After this fractionation of the heparin samples by means of brucine, the heparin activity proved to be increased in the material recovered from the brucine precipitate and decreased to 1/3-1/4 in the material obtained from the mother-liquor (see Table VI).

The purest preparations of heparin thus obtained showed rather more than 10 times the activity of the commercial preparations of Kahlbaum and of Hynson, Westcott and Dunning, Baltimore (see Table VII).

## EXPERIMENTAL.

The crude heparin was prepared from ox and horse liver as described by Charles and Scott. The material was first autolysed with toluene at 40° for 48 hours. The yield varied greatly as well in amount as in activity. It was not possible to make a thorough study of these details. A description of the details of the preparation and purification of the heparin will therefore be postponed until more experience has been gained.

The crude heparin was about 2 or 3 times as strong as the commercial preparations (see Table IV). In the first treatment with Lloyd's reagent about 70 % of the material was removed, without any considerable loss of activity, the product now being about 7-8 times as strong as commercial heparin (Kahlbaum). When this product was treated once or twice more with the adsorbing agent, the activity was but slightly increased. A considerable amount of contaminating material was however removed, as will be seen from Table II. The amount of protein possibly present was reduced from 11 to 2-3 %, as calculated from the N content of the samples, possible small amounts of ammonium salts being neglected. (Preparations Nos. 1-3 of Table II were obtained from the first preparation of the same table.)

The analysis of the material thus obtained is given in Tables I and II.

*Preparation of the trisulphuric acid by means of brucine.*

3 g. of preparation 4 were electrolysed in 170 ml. of water for 9 hours (at a current of 600 milliamps.), the temperature being kept below 25° (volume after dialysis 190 ml.). 150 ml. of this, corresponding to 2.4 g. of preparation 4, were neutralised with brucine and the excess of the base was removed with chloroform. The solution was kept in an ice-box and frozen repeatedly during the course of a week. The insoluble brucine salt was collected and washed with water in a centrifuge-tube. The weight of the air-dry substance was 1.8 g. The precipitate and the mother-liquor were treated separately with 20 ml. *N* NaOH and the brucine removed with chloroform. After neutralisation of the solution with HCl some magnesium chloride was added and the heparin precipitated with 1.5 vols. of acetone. On the next day the precipitate was dissolved in about 10 ml. of water and reprecipitated with about 100 ml. of acetone.

The yield of air-dry substance from the brucine precipitate was 580 mg. and from the mother-liquor 500 mg.

	Material recovered from brucine precipitate %	Material recovered from mother-liquor %

Acetic acid	1.46	—

In another experiment performed in the same way 2 g. of preparation 4 were electro dialysed. The insoluble brucine salt which separated on freezing the solution was dissolved in 200 ml. of boiling water. After filtration through a hot funnel, the clear solution was left standing for 2 days in the cold and frozen. The same procedure was repeated once more with the precipitate which settled out. From the brucine salt, 475 mg. of air-dry heparin were recovered (moisture: 8.35 %; S: 11.40 and 11.58 %, mean 11.49 %; on dry substance 12.54 % S).

The previous experiment yielded a substance containing 12.34 % S calculated on dry substance with a recovery of 30 % of the uronic acids present in the initial material (preparation 4).

In spite of the twice repeated reprecipitation of the brucine salt from water, the yield in this experiment was about the same, and the sulphur content differed but slightly.

The heparin from this experiment was mixed with the material recovered from 3 g. of another heparin sample treated in exactly the same way. The mixture was submitted to analysis.

*The Tollens-Lefèvre method of analysis.* There are many modifications of the Tollens-Lefèvre method for the determination of uronic acids. At first the technique of Dickson *et al.* [1930] was employed; during the course of the work it was found necessary to change many of its details.

The inlet air was freed of CO<sub>2</sub> in an effective wash-bottle with concentrated potassium hydroxide solution. A  $\Omega$ -shaped glass tube between the wash-bottle and the boiling flask rendered the escape of CO<sub>2</sub> backwards more difficult. Instead of a silver nitrate solution, solid silver sulphate suspended in water was kept in the trap for collecting the hydrochloric acid distilled over. The suspension was renewed after two analyses.

Seeing that the original technique of Dickson, Otterson and Link tended to give irregular figures 10–15 % too low in the analysis of known substances,

the influence of several factors was studied. More satisfactory results were only obtained after making the following changes.

The heating bath with Wood's alloy was kept at 145–150° during the hydrolysis, which was continued for 4 hours. Two microburners were used. The radiation of heat and the cooling by the refluxing liquid kept the temperature constant.

The strength of the hydrochloric acid was increased to 20 %. One volume of concentrated hydrochloric acid was mixed with 1 vol. of water. Owing to these changes somewhat more hydrochloric acid distilled over, but with satisfactory cooling and an efficient trap this disadvantage did not impair the results. On the contrary the yield of CO<sub>2</sub> agreed in almost every analysis with the calculated figure.

Furthermore, the excess of barium hydroxide was not titrated directly with 0.1N hydrochloric acid, but only after removal of the barium carbonate. In the direct titration there is a possibility that, even if the flask is shaken vigorously, the hydrochloric acid may react with the barium carbonate. The glass beads were quickly washed with CO<sub>2</sub>-free water in a suction funnel and the barium hydroxide was titrated in the suction flask. 0.1N HCl was added in excess, the solution boiled and titrated with 0.1N alkali against phenolphthalein.

For each analysis 250–300 mg. of the heparin preparations were taken. The reliability of the figures obtained was checked by analysing corresponding amounts of known substances before and after the analysis of the heparin. For this purpose a sample of chondroitinsulphuric acid prepared by the author's method [Jorpes, 1929] and an analytically pure crystalline sample of the glyceuronogalactose isolated by Butler and Cretcher [1929] from gum arabic were used. The figure calculated for the CO<sub>2</sub> in the Tollens-Lefèvre analysis of the chondroitinsulphuric acid was 6.5 %: found 6.50, 6.76, 6.57 %. The corresponding figure calculated for the glucuronogalactose, C<sub>12</sub>H<sub>20</sub>O<sub>12</sub>·2H<sub>2</sub>O is 11.22 %: found 11.16 %.

*The colorimetric determinations of hexosamine* were made by the method of Elson and Morgan, both on the mixed chondroitinsulphuric acids (preparation 1) and on the two samples of the supposed trisulphuric acid recovered from the insoluble brucine salt. The hydrolysate after the Tollens-Lefèvre analysis could be used for this purpose. Otherwise 50 mg. substance were hydrolysed in 7 ml. of 12 % hydrochloric acid for 3 hours over a free flame. The hydrochloric acid was removed by distillation. After neutralisation the volume was made up to 10 ml. and 0.4–1.0 ml. of this solution was used for a test. Generally three different concentrations were analysed in duplicate. Each time four different concentrations of glucosamine between 0.3 and 1 mg. were used also in duplicate as standards. The readings were plotted on a semilogarithmic paper, the logarithmic ordinates corresponding to the scale readings of the Zeiss step photometer. In spite of the great variations of the single analyses a good approximation to the hexosamine content was generally obtained. The method is a real advance on the older one of Zuckerkandl and Messiner-Klebermass [1931].

The weak alkaline solution with the acetylacetone (volume 3 ml.) was heated at 90° in a water-bath for half an hour. After cooling 5.5 ml. of 95 % alcohol were added. When the strongly acid Ehrlich reagent was added, air was blown through the solution and the volume was made up to 10 ml. (Filter S 53. Cups 0.5 cm.)

On the analysis of preparation 1 on three different days the figures 12.3, 12.9 and 14.4 % calculated on air-dry substance were found. The content of hexuronic acid, 17.23 %, would require 16 % hexosamine.

In the supposed chondroitintrisulphuric acid recovered from the insoluble brucine salt of the first experiment the figure 17.5% was found, for the acid recovered in the second experiment 16.9 and 17.3%. The figures calculated from the sulphur content were 19.6 and 19.8% respectively. For chondroitin-sulphuric acid treated in exactly the same way, the figures 22.3 and 20.5% were found on two different days; calculated 26.5%.

From these analyses it is evident that all the heparin samples contained 1 mol. of hexosamine per mol. of hexuronic acid.

The content of acetic acid was first determined by the method of Kuhn and Roth [1933], hydrolysis with alkali in methyl alcohol being employed. The figures obtained agreed well with those calculated and were used in the preliminary report [Jorpes, 1935] as evidence of the chondroitin structure of the preparations. The method had unfortunately been checked only on penta-acetylglucose. When the preparations were later on submitted to acid hydrolysis either with 25% sulphuric acid according to Levene and LaForge [1913] or with *p*-toluenesulphonic acid according to Friedrich and Rapoport [1932] a much lower acetyl content was found. All the analyses were therefore repeated with the last method. For chondroitinsulphuric acid figures which were only slightly (3%) too high were obtained by this method<sup>1</sup>.

For the sulphur determinations a sufficient amount of substance was taken to give a precipitate of barium sulphate weighing 20–40 mg., which was collected in a Neubauer-Gooch platinum-iridium microcrucible. Fusion was effected with sodium carbonate and potassium nitrate in porcelain crucibles.

The free sulphates were precipitated with barium chloride from 0.1 *N* hydrochloric acid solution. The precipitate could be filtered after one hour. In *N* hydrochloric acid 24 hours were necessary for a complete precipitation of the free sulphates.

After boiling for 1 or 2 hours with 10% hydrochloric acid the ester sulphates were split off. In preparation 2 of Table III 10.87 and 10.41% S were thus obtained after acid hydrolysis. The content of total S found on ignition was 11.17%.

Dialysis and electro dialysis were employed to remove the free sulphates and the positive ions from the heparin preparation. By electro dialysis the free acid and its alkaloid salts could easily be prepared.

The electro dialysis was performed with an apparatus constructed by E. Hammarsten [see Ågren, 1934]. 150–200 ml. of solution can be dialysed at one time. The solution is cooled by circulating acetone from a store flask with solid carbon dioxide.

200 mg. of preparation 2, dissolved in 10 ml. of water, were dialysed against water in a collodion sac. The outer fluid was changed daily during 3 days. Its volume was 1500 ml. The free sulphates found in it corresponded to 3.6% S in the sample, whereas the calculated figure was 3.46%. It did not contain any ester sulphates.

In two experiments with electro dialysis the heparin activity and the partition of the sulphates were observed. In the first experiment 200 mg. of preparation 2 were dissolved in 20 ml. of water and electro dialysed in a smaller apparatus for 2.5 hours. The current through the solution decreased from 500 to 380 milliamps. in half an hour and then remained constant. The sulphur of the free sulphates found in the anode liquor corresponded to 3.45% of the heparin sample (calculated 3.46%). In the inner cell no definite decrease of the heparin activity could be shown. In the anode liquor about 1% of the heparin activity could be traced, in the cathode liquor none.

<sup>1</sup> All these analyses were made by Sune Bergström, medical student.

When this experiment was repeated, the content of ester sulphates found in the cell after dialysis corresponded to 7.3 % of the sample (calculated 7.71 %). The sulphate-S found in the anode liquor corresponded to 3.2 %. On the liquor of the cell a thorough biological assay was made, showing no decrease in the anticoagulating activity (see Table V).

Thus neither the ester sulphates nor any heparin activity are lost during electro dialysis.

#### *The biological assay.*

Several attempts to use recalcified oxalate blood only showed the complete unreliability of this technique. As cats could not be used because of the expense involved, an attempt was made to use horse blood. The blood was filled directly from the vein into small test-tubes containing a certain amount of heparin

solution. The next step was to collect ox blood from the newly opened vessels at the slaughter house. This source of blood would evidently be the cheapest. Fortunately it proved to be quite satisfactory.

The blood was quickly decanted from paraffined vessels into series of small test-tubes (70 × 8 mm.) accommodated in a stand (30 × 4 × 2 cm.). The tubes had a capacity of 2.5 ml. and contained 0.2 ml. of heparin solution and a glass bead. Each stand contained 10 tubes fixed in holes. All the tubes could be simultaneously tightly closed by lowering the strongly attached cover, which was faced underneath with rubber. After the tubes were filled with the blood, the cover was quickly lowered and fixed, and the stand turned over several times. The time that elapsed before the glass bead no longer moved freely was taken as the time of coagulation. The tubes were left standing at room temperature. Readings were made at shorter intervals at the beginning, the last ones after 10, 12 or 24 hours. Between 10 and 20 stands were used each day.

The strength of an unknown sample was checked against a known in two ways. Either 5–6 stands were used for each sample of heparin, as in Table IV, or each stand contained 4 or 5 different concentrations both of the unknown and of the known sample, as is shown in the other tables.

The second method is to be preferred. The individual variations of the blood from different animals are hereby eliminated.

Differences smaller than 20–30% in the activity can hardly be expected to be distinguished with this technique.

In order to compare the purified heparin preparations with those of Charles and Scott, some experiments were performed on cats. Two of the animals gave a unitage of 450 and 540 per mg. of preparation 3. These experiments were performed by O. Wilander.

# DISCUSSION.

The first question to be answered is whether the substances analysed were identical with those of the previous investigators or not. At first it seemed unlikely that some of them should have overlooked the nitrogen content [Schmitz and Fischer, 1933]; and it is still more surprising that no mention is made in the literature of the sulphur. Only in one place is it mentioned that

heparin contains calcium and sulphuric acid, namely in the list added to the heparin (Kahlbaum). Here the routine analyst apparently, and not the research chemist, made the note.

There are several considerations which almost make the presence of these acidic groups in heparin necessary. First the ash amounting to 25–35% can hardly be explained without them. 1.5 vols. of acetone do not precipitate any sodium chloride added to the solution in order to facilitate the flocculation. Furthermore there is a striking similarity to the properties of chondroitinsulphuric acid. The most convincing evidence however is that the supposed chondroitintrisulphuric acid prepared from the liver shows such a strong heparin activity. It might be mentioned that preparations 1–5 of Tables I and II have a nitrogen content 1.63–1.93% and an ash content 38.4–41.5% of about the same order of magnitude as those of Charles and Scott. The general properties are quite identical. An attempt to test the heparin with cats gave also the same results, about 500 units per mg. substance.

Schmitz and Fischer describe a brucine salt stated to be crystalline, which they prepared from brucine sulphate and the barium salt of heparin. Their purified product was 32 times as active as the crude material obtained from Kahlbaum, which contained 8% of phosphorus, partly in nucleic acids. That the chondroitintrisulphuric acid forms an insoluble brucine salt and is more than 10 times as active as the commercial products of to-day, is also an indication of the identity of the different heparin samples.

The heparin preparations of Tables I and II have a uniform composition. Even if there is uncertainty as regards the uronic acid analysis, the assumption that the preparations consist of esters of sulphuric acid and chondroitin seems justified, and it is strongly supported by the results of the treatment with alkaloids. After the regeneration of the heparin from the alkaloid salts, preparations were again obtained with a similar composition except for the sulphur content, which now agreed exactly with the calculated figure for a chondroitintrisulphuric acid. The fractionation very strongly supports the view that the heparin activity belongs to this acid and not to any impurity. As there is not much hope of obtaining these acidic polysaccharides in a real crystalline state, the formation of a brucine salt, which can be reprecipitated after solution in boiling water, with the heparin activity not only preserved but increased as compared with the original material, seems at present to be satisfactory evidence of such a conclusion.

It is furthermore interesting to note that this supposed chondroitintrisulphuric acid, which apparently will prove to be the strongest acid of the animal body, bears a resemblance to all the synthetic anticoagulants, which are sulphonie or polysulphonie acids. Liquoid Roche is a salt of polyanetholesulphonie acid. Congo red, germanin, Chicago blue and chlorazole fast pink are all of them polysulphonie acids [*v. Huggett and Rowe, 1933–34*].

Even if the presence of the three sulphuric acid radicals makes it probable that the anticoagulating activity is located in them it is too early to make definite statements without further proof. In any case the acetamido-group seems to be of no importance for the heparin activity. In Table II the content of acetic acid varies between 2.24 and 4.10%, and in the trisulphuric acid it is only about 1.5%. Seeing that the content of uronic acid and hexosamine is almost constant in all the samples and slightly higher in the regenerated ones, it is evident that the acetyl group is split off during the preparation. At an early stage of the preparation, the material is heated to 70° at a slightly alkaline reaction, and during the regeneration from the brucine salt it is kept in *N*

sodium hydroxide solution for an hour or more. The heparin activity is not unfavourably influenced by this.

There is, however, one detail, which is in disagreement with the previous discussion, namely the negative naphthoresorcinol reaction. As stated by Charles and Scott it is negative even in concentrated solutions. If the reaction is performed simultaneously under quite similar conditions with heparin and chondroitinsulphuric acid, and the coloured substance is taken up in benzene, a marked difference will be seen. The test with heparin is almost or quite negative. With Howell's technique it was found positive. Furthermore the evolution of carbon dioxide on acid hydrolysis cannot be explained without the presence of a uronic acid. The similarity with the chondroitinsulphuric acid is also very striking. The only possibility, which could explain this discrepancy, is, that the ester sulphates may be united with the uronic acid, thereby retarding or preventing the colour formation.

#### SUMMARY.

Heparin, the anticoagulant from the liver, was purified by the method recommended by Howell and by Charles and Scott. After a certain degree of purity was reached, no further purification seemed possible. The samples were then analysed and found to contain about 17–19% of hexuronic acid and the amount of hexosamine calculated for 1 mol. of hexosamine per mol. of uronic acid. Acetic acid was found to be present.

The organic material of the heparin samples therefore seemed to be chondroitin.

The ash, amounting to 40% of the air-dry substance, consisted of magnesium sulphate. Only a small part of the sulphate in heparin could be precipitated with barium chloride, the remainder occurring as ester sulphate. For each mol. of chondroitin about 2.5 mols. of sulphur were found as ester sulphates.

These components together made up more than 90% of the heparin samples. The analysis thus indicated that the heparin was a chondroitinpolysulphuric acid.

On dialysing and electrodialysing both the ester sulphates and the heparin activity remained in the collodion sac or in the inner cell. On neutralising an electrodialysed solution of heparin with brucine and cooling the solution, an insoluble brucine salt slowly settled out. The substance recovered after removal of the brucine showed a stronger heparin activity than the previous samples and a content of uronic acid, hexosamine and ester sulphate corresponding to the composition of a chondroitintrisulphuric acid.

As regards the nature of the active group, the presence of the sulphuric acid radicals is the most prominent feature in the structure of heparin. All the synthetic anticoagulants, *e.g.* Liquoid Roche, germanin and Chicago blue are also strongly acidic, all of them being polysulphonic acids.

The author's thanks are due to Stiftelsen Therese och Johan Anderssons minne for several grants during the past years.

Grateful acknowledgment is made for the valuable assistance of Olof Wilander and Sven Linde during the performance of this work.

# CCXIV. SPECTROMETRIC MEASUREMENTS ON VARIOUS CAROTENOIDS.

By ALBERT EDWARD GILLAM.

*From the Chemistry Department, Manchester University.*

*(Received June 20th, 1935.)*

IN a previous investigation involving the spectrophotometric determination of carotene and xanthophyll in grass extracts [Gillam *et al.*, 1933] it was found that the determination of the blue colour with antimony trichloride (intensity of absorption at  $585\text{--}590m\mu$ ) gave higher values than were to be expected from the carotenoid content as determined by the yellow colour. It was considered possible that the discrepancy might be due to the presence of small amounts of carotenoids, differing from carotene and xanthophyll in being much more strongly chromogenic towards antimony trichloride. In addition to direct search for the disturbing factor, it was decided to determine the intensity of blue colour developed with antimony trichloride and various known carotenoids, with a view to finding such a highly chromogenic substance as has been postulated. As such a substance is not yet forthcoming, the present communication serves to record the quantitative visible and ultraviolet absorption spectroscopic data in chloroform, and visible data in chloroformic antimony trichloride, for such pure carotenoids as have been available, with a view to their subsequent use in the spectrometric determination of these pigments.

The determinations were made photographically for the most part, using a Hilger E 3 quartz spectrograph and either a Spekker or a sector photometer, but absorption in the visible was also determined on a Hilger-Nutting visual spectrophotometer (Table I). The examination of the antimony trichloride blue colours was also made with this instrument, using the technique previously applied in the case of vitamin A [Heilbron *et al.*, 1931]. The antimony trichloride reagent was made up as a saturated solution in alcohol-free chloroform, one drop of acetic anhydride being usually added in each test to render the solutions optically clear. The concentrations were so arranged that the ratio of antimony trichloride to pigment solution was always more than 10 to 1 and, when the colours were transient, the values recorded were the mean of many separate mixings with the intensity measurements following immediately.

Euler *et al.* [1932] have recorded the visible absorption spectra of a number of carotenoids in both chloroform and antimony trichloride solution, but intensities were not measured.

Through the kindness of Prof. Chibnall and Dr Pollard, of the Imperial College of Science, I was able to examine a pure specimen of  $\beta$ -carotene from cocksfoot grass. This had no detectable optical activity, and m.p.  $182^\circ$  (corr.). Its intensity of absorption was some 10% higher than that of the best sample previously examined [Gillam *et al.*, 1933]. The new value of  $E_{1\text{cm}}^{1\%}$  2200, in chloroform solution, must therefore be adopted for future spectrophotometric carotene determinations. In light petroleum (b.p.  $60\text{--}80^\circ$ ) the corresponding value was 2500.

The typical carotenoids, carotene and lutein exhibit absorption spectra consisting of a group of bands in the visible spectrum, a single band at  $330\text{--}350m\mu$

and another at  $270\text{--}280m\mu$  (Fig. 1). Lycopene (Fig. 2) follows the same general outline, but differs in that the two simple ultraviolet bands are each resolved into two components. The resolution is only shown easily when a light source with a continuous spectrum is used (*e.g.* an under-water tungsten spark or a hydrogen tube). The curves recorded by Pummerer, *et al.* [1929], do not show this resolution (solvent *cyclohexane*).

Fig. 1. Lutein (*ex Tagetes*) in  $\text{CHCl}_3$ .

Fig. 2. Lycopene in  $\text{CHCl}_3$ .

Fig. 3. Zeaxanthin in  $\text{CHCl}_3$ .

Fig. 4. — Violaxanthin in  $\text{CHCl}_3$ ; ---- Violaxanthin in  $\text{CHCl}_3$  after partial decomposition by ultraviolet rays.

Violaxanthin in dilute solution in chloroform appears to be more stable to light and air (in glass vessels) than carotene or lutein. On the other hand, its chloroform solution is very sensitive to short-wave ultraviolet rays. This was made evident in determining the ultraviolet absorption spectrum of the solution, when the radiations from an iron-nickel arc, even at a distance of 5 feet, were sufficient to change the colour of the solution from yellow to green in about 30 minutes. By irradiation of a dilute solution (about 0.001 %) with a quartz mercury vapour lamp, it was observed that:

(a) In a quartz vessel, the solution rapidly turns green, then bluish green and finally colourless.

(b) The blue solution, which with the yellow of the unchanged violaxanthin presumably gives the green colour, exhibits two narrow but intense absorption bands with maxima at  $411$  and  $438m\mu$  (Fig. 4).

(c) In glass apparatus the solution is unchanged in colour even with exposures up to 30 minutes at 8 in. from the lamp. The ultraviolet rays which bring about the photochemical change must therefore be of shorter wave-length than  $325m\mu$ , the approximate short-wave limit of transmission of glass.

Table II. *The colour and absorption spectra of the antimony trichloride solutions of the carotenoids.*

Substance	Colour	Absorption spectra	Intensity of absorption $E_{1\text{cm}}^{1\%}$			Effect of adding 7-methylindole before the $\text{SbCl}_3$
			615 $m\mu$	585 $m\mu$	420	
$\beta$ -Carotene ( <i>ex</i> cocksfoot grass)	Slate-blue	A single band at 590 $m\mu$	—	—	—	None
isoCarotene	Slate-blue	Single band at 583–587 $m\mu$	—	—	370	—
Lycopene	Blue	Strong end-absorption in the red, weak inflection near 585 $m\mu$	200	200	200	—
Lutein ( <i>ex Tagetes</i> )	Blue (forms slowly)	Clear band at 617 $m\mu$ and inflection 580–590 $m\mu$ , strong absorption in the red beyond 700 $m\mu$	315	230	230	No 617 $m\mu$ band. Bands at 585 and 545 $m\mu$
Lutein ( <i>ex</i> nettles)	Blue (forms slowly)	Clear band at 619 $m\mu$ and inflection 580–590 $m\mu$ ; strong absorption in the red	300	230	230	
Zeaxanthin	Blue	Bands at 621 and 587 $m\mu$ ; the latter forms first and fades rapidly	370	330	330	Single band 583 $m\mu$ does not now fade rapidly
Violaxanthin	Blue (immediate; contrast lutein)	Clear band at 585 $m\mu$ , ill defined one at 615 $m\mu$ ; the first decreases rapidly whilst the latter increases	340	350	—	—
Fucoxanthin ( <i>ex Fucox vesiculosus</i> )	Blue	End-absorption in the red only	290	190	—	None
Astacene ( <i>ex lobsters</i> )	Transient violet-blue	Broad indistinct band near 590 $m\mu$	—	1000 (At 590 $m\mu$ )	—	None
Azafurin methyl ester	Deep royal blue	End-absorption in the red; broad but definite band at 595–600 $m\mu$	—	—	650 (At 596 $m\mu$ )	—
*Vitamin A	Deep blue	Clear maximum 617–620 $m\mu$ ; masked maximum 580–583 $m\mu$	5000	2000	2000	Single band at 583 $m\mu$

\* Data by Heilbron and Morton cited by Carr and Jewell [1933].

The colour change depends upon the decomposition of the chloroform by the short-wave ultraviolet rays with the production of hydrogen chloride, which then produces the blue colour with the violaxanthin. As might be expected, the blue colour reverts to yellow on the addition of alkali. These observations suggest a variation of the test for violaxanthin, in which it gives a blue colour with 25 % hydrochloric acid, the variation being to produce the colour in the chloroform solution by exposure to short-wave ultraviolet rays (mercury vapour lamp).

The blue colour obtained by the action of antimony trichloride on lutein has been examined by Euler *et al.* [1932] and by Goldhammer and Kuen [1933], both of whom record only one absorption maximum at  $586m\mu$ . Under the experimental conditions used in this investigation the absorption band characteristic of the blue solution was found to lie at  $617m\mu$  with only a subsidiary or masked maximum near  $586m\mu$  and strong absorption in the red. These maxima were obtained with four different crystalline samples of lutein from various sources and were also typical of the xanthophyll fractions of several species of grass [Gillam *et al.*, 1933]. The visual determination of the wave-length maxima is supported by the intensity measurements (Table II).

Fig. 5. Fucoxanthin (*ex Fucus vesiculosus*) in  $\text{CHCl}_3$ .

Fig. 6. Azafurin methyl ester in  $\text{CHCl}_3$ .

Fig. 7. Astacene in chloroform.

It is interesting to note that the three hydroxy-polyenes, vitamin A, lutein and zeaxanthin, give colours with antimony trichloride, all of which exhibit an absorption band at  $617\text{--}620m\mu$  and another near  $585m\mu$ . The similarity is only qualitative since vitamin A shows by far the strongest absorption bands, being some fifteen times as chromogenic as either of the two xanthophylls. It has been shown that the addition of 7-methylindole to a vitamin A extract

before the antimony trichloride inhibits the formation of the 617–620  $m\mu$  band completely, leaving only a maximum at 583  $m\mu$  [Emmerie *et al.*, 1931; Morton, 1932]. The two xanthophylls behave in a similar manner after this treatment, lutein showing two maxima at 585 and 545  $m\mu$  and zeaxanthin showing only one at 583  $m\mu$ .

The author is indebted to Prof. R. Kuhn, who made this investigation possible by gifts of the necessary carotenoid pigments, and to Prof. I. M. Heilbron for his interest and for several additional carotenoid samples. Thanks are also due to Messrs Imperial Chemical Industries, Ltd., for financial assistance.

# CCXV. THE ALKALINE PHOSPHOMON- ESTERASE OF THE MAMMARY GLAND.

BY SYDNEY JOHN FOLLEY AND HERBERT DAVENPORT KAY.

*From the National Institute for Research in Dairying, University of Reading.*

*(Received July 1st, 1935.)*

It has been known for some time [Kay, 1925] that the mammary gland contains an active phosphomonoesterase of the alkaline type, *i.e.* a phosphomonoesterase with an optimum activity in the neighbourhood of  $p_H$  9, superficially similar to that present in kidney or bone. The mammary enzyme is of peculiar interest since it occurs in an organ which is continually synthesising phosphoric esters (caseinogen and the acid-soluble phosphoric esters of milk) from the inorganic phosphate of the circulating blood [Blackwood, 1934; Lintzel, 1934; Graham and Kay, 1934]. The net effect of this mammary enzyme (if it is actually concerned with the formation of phosphoric esters *in vivo*) is therefore, unlike that of the phosphatase of kidney and bone, a synthetic, anabolic one.

Except for the findings of Borst [1932], who showed that mammary tissue would hydrolyse adenylic acid, and of Brenner [1932] who showed that inorganic phosphate was liberated during the autolysis of mammary tissue, the enzyme has received little attention since its discovery. It seemed to us that this enzyme, in view of its close relationship to synthesis, might possibly possess unusual specific properties when compared with the better known phosphatases. We were also interested in its relationship to the phosphatase of milk which is now of value in the dairy laboratory as an index of the efficiency of pasteurisation. We decided to study its properties more closely, with a recently developed technique (which appears to us to have definite advantages over methods formerly used) and establish its identity or otherwise with other "alkaline" phosphomonoesterases.

## EXPERIMENTAL.

### *Preparation of mammary gland extracts.*

The guinea-pig was chosen as a source of mammary tissue chiefly for the reasons that animals in a suitable stage of lactation are readily obtainable, and that the mammary tissue is localised in well-defined glands situated on the posterior portion of the abdomen. These glands can be quickly and cleanly dissected out from the bodies of lactating females. They come away whole with no adherent extraneous tissue except a little subcutaneous fat which is easily removed.

The guinea-pigs were killed with chloroform and to facilitate dissection the hair covering the abdomen was removed with a BaS depilatory paste, which was carefully washed away before commencing dissection. When dissected out the glands were washed free from blood and as much milk as possible removed by squeezing between filter-papers. They were then weighed on an air-damped balance. Each gland was cut into small pieces and ground to a uniform paste with a little sand and chloroform water in a glass mortar. Transferred to a measuring vessel the mixture was made up to such a volume with distilled water that 10 ml.  $\equiv$  1 g. of original tissue. After standing at room temperature for 18-24 hours with occasional shaking, the solid residue was removed by filtration

through cotton wool and the extract stored in the refrigerator at  $0^{\circ}$ . Under such conditions the phosphomonoesterase activity of these extracts remained unimpaired for a considerable time. No attempt at further purification of the extracts was made beyond dialysing some of them at  $0^{\circ}$  for experiments on the action of Mg.

*Method of estimation of phosphomonoesterase activity.*

King and Armstrong [1934] have introduced a method for the clinical determination of the phosphomonoesterase content of blood serum, plasma and bile, in which disodium phenyl phosphate, buffered to  $p_H$  8.9 with sodium diethylbarbiturate, is used as substrate, the phosphatase activity being measured by the amount of phenol set free in 30 mins. at  $37^{\circ}$ . The short period of hydrolysis is made possible by the facts that monophenyl phosphate is enzymically hydrolysed more rapidly than glycerophosphate and that for every mg. of inorganic phosphate liberated about 3 mg. of phenol are set free. The enzymic activities so determined are clearly likely to be nearer to true initial velocities of hydrolysis than the values obtained after a hydrolysis lasting some hours, hence an attempt was made to utilise the method of King and Armstrong for work on the phosphomonoesterase of the mammary gland. In practice certain modifications in detail were found to result in greater accuracy and a modified method was developed which can be usefully applied to the investigation of tissue phosphomonoesterases as well as those of blood, milk *etc.* These modifications are described below.

*Buffer.* For the work to be described a buffer operating in the  $p_H$  range 8–11 at  $37^{\circ}$  was required. Borate buffer was found to interfere with the determination of phenol. Glycine buffer was finally chosen in spite of the fact that Bakwin and Bodansky [1933] have stated that glycine retards somewhat the hydrolysis of glycerophosphate by kidney phosphomonoesterase.

*Colorimetric estimation of phenol.* For the estimation of phenol King and Armstrong found the reagent of Folin and Ciocalteu [1927] to be more satisfactory than that of Theis and Benedict [1924], and this has also been our own experience. The blue colour produced when a solution containing phenol together with the phosphotungstomolybdate reagent of Folin and Ciocalteu is made alkaline with  $Na_2CO_3$  lends itself to accurate colorimetry provided that attention is paid to certain details now to be dealt with.

*Effect of temperature on colour development.* Each curve shown in Fig. 1 was obtained by adding 2.5 ml. of saturated  $Na_2CO_3$  to 10 ml. of a solution containing 0.1 mg. phenol and 1 ml. of Folin and Ciocalteu's reagent in 10 ml. and measuring the rate of blue colour development at the stated temperature by means of a Lovibond tintometer. It can be seen that at  $20^{\circ}$  the blue colour does not reach its final intensity after 90 mins. Peters and Van Slyke [1932] direct that the warm solutions (approx.  $30^{\circ}$ ) be compared in the colorimeter 20 mins. after the addition of  $Na_2CO_3$ , presumably standing at room temperature the while. If these directions are followed, measurements can only be dubious as very little blue colour has by then appeared.

At temperatures much exceeding  $40^{\circ}$  a white precipitate appears [v. Rakestraw, 1923] and accurate colorimetric comparison is precluded.

The best compromise is attained by reducing the amount of the phenol reagent used for each estimation to 4 ml. and by developing the blue colour by warming at  $37^{\circ}$  for exactly 45 mins. Fig. 1 shows that after 45 mins. at  $37^{\circ}$  over 95% of the final colour intensity has been reached and further increase is

very slow. Experience has shown that accurate colorimetric measurements can be made if unknowns and standards are worked up simultaneously and subjected to this standard procedure.

Fig. 1.

Fig. 1. Rate of blue colour development at different temperatures.

Fig. 2.

Fig. 2. Effect of alkalinity and of glycine on blue colour intensity. A, 3.3 %  $\text{Na}_2\text{CO}_3$ ; 0.11 % glycine; B, 3.3 %  $\text{Na}_2\text{CO}_3$ ; C, 2.7 %  $\text{Na}_2\text{CO}_3$ ; D, 2.2 %  $\text{Na}_2\text{CO}_3$ .

*Influence of alkalinity on the blue colour.* The curves in Fig. 2 express the rate of blue colour formation in presence of different concentrations of  $\text{Na}_2\text{CO}_3$ , the solutions being in other respects identical except where otherwise stated. The final colour intensity obviously depends on the alkalinity of the solution, and this should be carefully controlled. Saturated  $\text{Na}_2\text{CO}_3$  as suggested by King and Armstrong may be used but it is preferable to use an unsaturated solution containing 14 %  $\text{Na}_2\text{CO}_3$ .

*Effect of buffer solutions on the blue colour.* On investigation, sodium diethyl-barbiturate proved to have very little effect on the intensity of the blue colour. Glycine, on the other hand, markedly increases the final blue value (curve A in Fig. 2). If, therefore glycine buffer be used for phosphatase estimations it is necessary to compensate for its intensifying effect on the phenol colour by using a standard which contains the appropriate concentration of glycine.

*Modified method for phosphomonoesterase determination.* For each determination a stoppered test-tube containing 5 ml. of 0.1 M glycine buffer and 5 ml. of a solution of disodium monophenyl phosphate of the requisite strength is warmed for a few minutes in a water thermostat at 37° and 1 ml. of a suitably diluted mammary extract added from an Ostwald pipette. After a measured time, which is usually 30 mins. but can be shortened if desired, the tube is plunged into iced water and 4 ml. of a 1 in 3 dilution of Folin and Ciocalteu's reagent are added. After shaking and standing for 30 mins. the solution is filtered through a No. 42 Whatman paper and 10 ml. of filtrate pipetted into a dry tube. For each determination a blank is run in which the enzyme is inactivated by the immediate addition of Folin and Ciocalteu's reagent which should contain 0.15 mg. phenol in 4 ml. to bring up the faint colour to a measurable intensity. In addition blanks intended to reveal the amount of phenol (if any) produced by incubating the buffer with the substrate and the enzyme with the buffer may be set up. Such corrections have been found to be negligible and are usually omitted. Using an accurate pipette, 2.5 ml. of 14 %  $\text{Na}_2\text{CO}_3$  solution are added to the

filtrates from unknown and blanks and also to a tube containing 10 ml. of the standard solution described below. The tubes are shaken and placed in the thermostat at 37° for 45 mins., after which they are cooled and read off in the colorimeter.

The standard solution contains, in 50 ml., 5 ml. of a stock phenol solution containing 0.1 mg. phenol per ml., 13½ ml. of a 1 in 3 dilution of Folin and Ciocalteu's reagent and 16½ ml. of glycine buffer. If necessary, weaker standards containing 4, 3 or 2 ml. respectively of stock phenol solution may be prepared. King and Armstrong direct that the standard should be freshly prepared each day. We have found that standards will keep satisfactorily for at least 3 days at room temperature but should be renewed on the fourth day.

The above method may be used for the determination of blood serum or plasma phosphomonoesterase, the plasma or serum being diluted with an equal volume of saline. Alternatively 0.5 ml. of undiluted serum or plasma may be taken and 4.5 ml. of Folin and Ciocalteu's reagent used.

Duplicate phosphatase estimations which agree to within  $\pm 1\%$  can readily be carried out.

*Hydrogen ion concentration.* The experiments described in this paper were done in the  $p_H$  range 8–11 in presence of 0.045 *M* glycine buffer. The  $p_H$  of a glycine buffer varies considerably with temperature so that all control measurements of  $p_H$  except where otherwise stated were made with the hydrogen electrode at 37°. Between  $p_H$  8.9 and 10.0 the buffers were sufficient to maintain the acidity of the solutions at the required value. Above  $p_H$  10.0 electrometric measurement of the  $p_H$  of control duplicates was necessary.

*Presence of a phosphomonoesterase in mammary tissue.*

All guinea-pig mammary glands which have been examined have been found to possess very appreciable phosphomonoesterase activity, in some cases to a degree greater than that of guinea-pig kidneys. In Table I the activities of

Table I.

Extract	Units phosphomono- esterase per g. wet tissue	Weight of glands g.	Presence of milk in glands
M 12	11.3	2.90, 3.34	+
M 13	14.8	2.4, 2.3	+
M 14	6.4	6.1, 5.3	+
M 16	13.5	4.4, 4.3	Probable
M 15	21.4	1.05, 1.05	—
M 17	42.2	1.5, 1.3	—
M 18	33.5	1.7, 1.6	—
M 8	48.5	1.2, 1.3	—
Kidney 8	39.7	—	.
Kidney 12	28.5	—	.

eight typical extracts are given, together with the weights of the glands from which they were made. The activities are calculated per g. wet weight of original mammary tissue.

It will be seen that those glands which were heavy and showed signs of active milk secretion were less active per g. than small glands that showed no signs of milk secretion. Indeed, Table I shows that the latter tissue is at least as rich in phosphomonoesterase as were the kidneys taken from two guinea-pigs.

The difference in phosphomonoesterase activity per g. which appears to exist between functional and non-functional mammary tissue may be due, in

part at any rate, to the presence of milk, which is relatively poor in phosphomonoesterase, in the cells and alveoli of the large lactating glands. On the other hand it is possible that mammary tissue which is not actively secreting milk may indeed be intrinsically richer in phosphomonoesterase than secreting tissue. This question will be investigated further.

*Time course of mammary gland phosphomonoesterase hydrolysis.*

The rates of hydrolysis of disodium phenyl phosphate by mammary gland extracts at  $37^\circ$  and  $p_H$  10.0 are plotted in Fig. 3 for substrate concentrations of  $0.0045 M$  and  $0.00023 M$ . Both curves can be considered to be linear since the points near the origin are necessarily subject to considerable experimental error. It may be concluded therefore that for reaction times up to 30 mins. at least, the amount of hydrolysis affords a good measure of the initial reaction velocity which, under given conditions, is the quantity defining the activity of an enzyme under those conditions. This holds equally for 2.8% hydrolysis of substrate (curve A, 30 mins.) and for 15% hydrolysis (curve B, 30 mins.).

Fig. 3.

Fig. 4.

Fig. 4. Optimum  $p_H$  for hydrolysis of phenyl phosphate under different conditions. A, Mammary gland phosphomonoesterase; substrate concentration  $= 0.00023 M$ . B, Mammary gland phosphomonoesterase; substrate concentration  $= 0.0045 M$ . C, Kidney phosphomonoesterase; substrate concentration  $= 0.0045 M$ .

*Mammary gland phosphomonoesterase activity and  $p_H$ .*

The activities of a preparation of mammary gland phosphomonoesterase at various  $p_H$  values in presence of  $0.0045 M$  disodium phenyl phosphate are plotted in Fig. 4. The hydrolysis was found to proceed optimally at  $p_H$  10.0. This is in agreement with the result of Asakawa [1929] who reported  $p_H$  9.9 for optimum hydrolysis of this substrate by kidney phosphomonoesterase but differs from that of Roche [1931] who found  $p_H$  8.4–8.6 for serum phosphomonoesterase. The same result for mammary gland phosphomonoesterase was obtained when the activity determinations were based on reaction times of 15, 30 or 60 mins. In the same diagram is given the  $p_H$ -activity curve for the

hydrolysis of 0.000227  $M$  substrate by mammary gland phosphomonoesterase. Under these conditions the optimum becomes  $p_H$  9.3 indicating that the Michaelis constant for this enzyme varies with  $p_H$ . Asakawa [1928], studying the hydrolysis of glycerophosphate by kidney phosphomonoesterase, observed a change in  $p_H$  optimum at different substrate concentrations and was confirmed by Jacobsen [1933].

Roche gives no details of the hydrolysis time or of the substrate concentration, but it is not unlikely that the discrepancy between his result and our own may be due to the following reasons. The true  $p_H$ -activity curve for bone phosphomonoesterase is probably modified by alkaline inactivation of the enzyme, a process shown by Martland and Robison [1927] to proceed with rapidity at 37° above  $p_H$  8 as the alkalinity is increased. A similar result has been obtained for mammary gland phosphomonoesterase (see below). It is thus to be expected that a  $p_H$ -activity curve plotted from activities based on amounts of hydrolysis produced in a given time, would show, if that period of time were large, a  $p_H$  optimum lower than if the curve were drawn from true initial velocity determinations.

It is noteworthy in this connection, that though the optimum  $p_H$  for the enzymic hydrolysis of glycerophosphate in the concentrations ordinarily used is usually given as 8.9 [v. Kay, 1932], Robison [1932] has reported optima as high as  $p_H$  9.5 for short period hydrolyses of glycerophosphate by bone phosphomonoesterase.

The shift of the  $p_H$  optimum towards the acid side in low substrate concentrations is understandable on the supposition that the substrate, in concentrations sufficient to saturate the enzyme, protects the latter from the inactivating effect of excess of  $OH^-$  ion. Later it will be shown that whilst the enzyme in the concentration used is fully combined with monophenyl phosphate when the latter is present in 0.0045  $M$  concentration, this is not so when the concentration is as low as 0.000227  $M$ . Alkaline inactivation with its consequent effect on determinations of the  $p_H$  optimum will thus probably proceed at a higher rate under the latter conditions.

Fig. 4 also shows the  $p_H$ -activity curve for the hydrolysis of 0.004545  $M$  phenyl phosphate by an extract of guinea-pig kidney. The optimum  $p_H$  for kidney phosphomonoesterase is identical with that for the mammary gland enzyme under the same conditions. Further, when it is remembered that in both cases the  $p_H$  optimum decreases with decreasing substrate concentration it is evident that as regards hydrogen ion activation the two enzymes behave similarly.

*Relation between mammary gland phosphomonoesterase activity  
and substrate concentration.*

According to the theory of Michaelis and Menten [1913] an enzyme combines with its substrate to form a compound which dissociates into enzyme and reaction products. The relation between enzymic activity and substrate concentration should then be represented by

$$\frac{v}{V} = \frac{s}{s + K_m},$$

where  $v$  is the initial velocity of hydrolysis,  $V$  is a constant,  $s$  is the substrate concentration and  $K_m$  (the Michaelis constant) is the dissociation constant of the enzyme-substrate compound.

The activity of a preparation of mammary gland phosphomonoesterase in the presence of substrate concentrations varying from 0.0001136 to 0.1818  $M$

has been investigated at  $37^\circ$  and  $p_H$  10.0 and the results are plotted graphically in Fig. 5 which also shows the results of a similar experiment on guinea-pig kidney phosphomonoesterase. The experimental results are represented by points, while the unbroken curves are plotted from Michaelis and Menten's equation,  $K_m$  being 0.0006 in each case.

Fig. 5. Relation between substrate concentration and initial rate of enzymic hydrolysis of phenyl phosphate at  $p_H$  10.

It would appear that for substrate concentrations up to  $0.009M$  both enzymes behave in accordance with the theory of Michaelis and Menten, the Michaelis constant being the same for each. At higher substrate concentrations, however, the initial velocities are less than would be expected from the theory.

Haldane [1930] has put forward a theory which attempts to account for cases in which high substrate concentrations cause inhibition of enzymic activity. This theory postulates that for hydrolysis to occur, the enzyme  $E$  must first unite with the substrate  $S$  at two points. (Such a compound  $ES$  is the only one which breaks down into the end products of the reaction.) There is, however, a certain proportion of the enzyme molecules which unite with one substrate molecule at each of the two active points, to give  $ES_2$  which, though in equilibrium with  $E$  and  $S$ , does not break down into the final products of hydrolysis. With increasing substrate concentrations there would at any given moment be a larger and larger proportion of such unions. But according to the theory such unions do not result in hydrolysis, therefore the initial velocity of hydrolysis will fall off as they become more numerous. Mathematical development of the theory gives the law

$$v = \frac{k}{1 + \frac{K_1}{s} + \frac{s}{K_2}},$$

where  $v$  = initial velocity of hydrolysis,  $K_1$  and  $K_2$  are the Michaelis constants of the reactions (i)  $E + S \rightarrow ES$  and (ii)  $E + S + S \rightarrow ES_2$ , and  $k$  is a third composite constant containing the velocity constant of the slow reaction  $ES \rightarrow E + P$  ( $P$  = products), and the total concentration of the enzyme in the system (also constant). In Fig. 6 the experimentally determined activities of guinea-pig kidney phosphomonoesterase and mammary gland phosphomonoesterase in presence of different concentrations of substrate reduced to the same scale by

Fig. 6. Relation between substrate concentration and initial rate of enzymic hydrolysis of monophenyl phosphate at  $p_H$  10. • Kidney phosphomonoesterase. x Mammary gland phosphomonoesterase.

Fig. 7.

Fig. 7. Effect of  $p_H$  on relationship between substrate concentration and initial rate of hydrolysis of phenyl phosphate by mammary gland enzyme.

Fig. 8.

Fig. 8. Relationship between substrate concentration and initial rate of hydrolysis of phenyl phosphate by mammary gland enzyme at  $p_H$  8.9.

suitable choice of values for  $k$  in each case, are represented by the points, whilst the unbroken line is that given by the equation

$$V = \frac{k}{1 + \frac{0.00066}{s} + \frac{s}{0.125}}.$$

Evidently the behaviour of both enzymes accords well with the theory of Haldane, and their properties are similar in that for each of them  $K_1 = 0.00066$  and  $K_2 = 0.125$ .

Interesting results were obtained when the relation between substrate concentration and activity of mammary gland phosphomonoesterase was investigated at higher H ion concentrations. In Fig. 7 are shown curves expressing the results obtained at  $p_H$  10.0, 9.5 and 8.9 respectively, the same enzyme preparation in equal concentrations being used for each experiment. The results show that with decreasing  $p_H$ ,  $K_1$  and  $K_2$  become smaller, the optimum substrate concentration diminishes and the activity of the enzyme at the optimum decreases. The existence of an optimum substrate concentration for phosphomonoesterase hydrolysis, an optimum that varies with  $p_H$ , is clearly brought out by the curves, which also illustrate the change in optimum  $p_H$  referred to above. The curves corresponding to  $p_H$  8.9 and 9.5 are by no means as symmetrical as Haldane's theory requires but their general shape is in agreement with the theory. In Fig. 8 the experimental points obtained at  $p_H$  8.9 are compared with the line

$$v = \frac{k}{1 + \frac{0.001}{s} + \frac{s}{0.0196}}$$

with which they give a reasonably good fit.  $K_1$  and  $K_2$  have now the approximate values 0.001 and 0.02 respectively.

The relation of these results to those of other workers for phosphomonoesterases from different sources will now be considered. Martland and Robison [1927] were unable to detect any difference in glycerophosphatase activity of bone extracts with substrate concentrations between 0.003 and 0.3  $M$ . Roche [1931], working with a range of glycerophosphate concentrations from 0.006 to 0.32  $M$ , found an increase in the activity of serum phosphomonoesterase with increasing substrate concentrations. Jacobsen [1932], in the course of a study of the retarding action of inorganic phosphate on the hydrolysis of glycerophosphate by kidney phosphomonoesterase, showed that over a certain range the initial velocity of hydrolysis depended on the substrate concentration and he was able to estimate  $K_m$  at  $p_H$  8.7 as approximately 0.0001 (substrate concentrations in molarity). He also showed that if the initial concentration of inorganic phosphate were made approximately equal to the initial substrate concentration, *i.e.* if the competitive phosphate inhibition were kept constant, the initial velocity of hydrolysis attained a maximum at a substrate concentration of approximately 0.0014  $M$  at  $p_H$  8.7. This value may be compared with our value for the optimum concentration of phenyl phosphate for hydrolysis by mammary gland phosphomonoesterase at  $p_H$  8.9 which was found to be 0.0009  $M$  (Fig. 7). The good agreement between these values is striking evidence in favour of the identity of the phosphomonoesterases from the two sources.

Later, Jacobsen [1933] studied the influence of  $p_H$  on  $K_m$  and found that the latter varies with  $p_H$ , increasing as the acidity is reduced. If Jacobsen's values of  $K_m$  at various  $p_H$  values are extrapolated,  $K_m$  at  $p_H$  10 comes out at approximately 0.0045 (substrate concentrations in molarity) which is

about seven times the value of  $K_m$  found by us for the hydrolysis of phenyl phosphate by mammary gland phosphomonoesterase at  $p_H$  10.0. Assuming the identity of the two phosphomonoesterases (see below) it is thus evident, if  $K_m$  is to be regarded as a dissociation constant, that the "alkaline" phosphomonoesterase has a much greater affinity for phenyl phosphate than for glycerophosphate, which accords well with the fact that the former substrate is hydrolysed by it more rapidly than the latter.

*The relation between hydrogen ion concentration and the stability of mammary gland phosphomonoesterase.*

A mammary gland extract diluted so as to be twice the strength required for activity determinations was divided into 5 ml. portions which were titrated to various hydrogen ion concentrations with  $N/50$  NaOH or  $N/50$  HCl. In each case the total volume of solution was brought up to 7.5 ml. by the addition of water. The tightly stoppered tubes containing the solutions were set in the thermostat at  $37^\circ$  for a measured time after which they were cooled in iced water and their contents neutralised and then made up to 10 ml. with water.

The  $p_H$  values of duplicate solutions were measured at  $20^\circ$  with a glass electrode used in conjunction with a Cambridge electrometer valve direct reading  $p_H$  meter.

The activities of the neutralised extracts were determined at  $p_H$  10 in the usual way. The results show that the enzyme undergoes rapid inactivation at  $p_H$  10 and  $37^\circ$ . It is therefore theoretically more satisfactory to determine comparative activities at an acidity at which the enzyme is stable, so that the concentration of enzyme shall remain constant throughout the determination.  $p_H$ -activity curves show however that the enzyme has very little activity at its  $p_H$  of maximum stability and thus many hours of hydrolysis are necessary for comparative activity determinations in the neighbourhood of this  $p_H$ . Nevertheless, in one experiment, in addition to the activity determinations performed as usual, the activities were also determined at  $p_H$  8 in presence of diethylbarbiturate buffer, 19 hours' hydrolysis at  $37^\circ$  being necessary. The curve so obtained was of similar shape to that obtained in activity determinations at  $p_H$  10 (curve A, Fig. 9).

Fig. 9. Stability of mammary gland phosphomonoesterase at different acidities.

The two curves shown in Fig. 9 were obtained with different enzyme preparations. In one case (curve *A*) the portions of enzyme were kept at the stated  $p_H$  values for 2 hours, whilst for curve *B* the inactivation time was 3 hours. In the latter case a  $p_H$ -stability curve with a sharp optimum was obtained, which indicates that mammary phosphomonoesterase has a narrow zone of maximum stability around  $p_H$  7, the enzyme, at least in absence of its substrate, being rapidly inactivated at  $37^\circ$  on either side of this zone. The much flatter optimum corresponding to the shorter time of inactivation was to be expected. Bone phosphomonoesterase was found, in a general way, to behave similarly by Martland and Robison [1927], who showed that it was inactivated at  $37^\circ$  at alkalinities above  $p_H$  8 and at acidities greater than  $p_H$  6. The stability of kidney phosphomonoesterase at various hydrogen ion concentrations was investigated by King [1931], who obtained a curve very similar in shape to curve *B* in Fig. 8 with the optimum located near  $p_H$  7. In respect therefore of the effect of hydrogen ion concentration on stability, the phosphomonoesterases of mammary gland and kidney seem to behave identically.

*Effect of magnesium on mammary gland phosphomonoesterase.*

For the investigation of this phenomenon, mammary gland extracts from which most of the magnesium had been removed by dialysis were required. These were prepared as follows. 5 ml. of extract were pipetted into a collodion

Fig. 10.

Fig. 11.

Fig. 10. Effect of Mg concentration on rate of hydrolysis at  $p_H$  10 of monophenyl phosphate by mammary gland phosphomonoesterase.

Fig. 11.  $p_H$ -activity curve for mammary gland phosphomonoesterase fully activated by addition of Mg.

sac which was then tied off as near as possible to the surface of the liquid. The sac and contents, dry on the outside, were weighed on an air-damped balance before and after dialysis so that correction for dilution of the extract during

dialysis could be made. Dialysis at  $0^\circ$  against frequently renewed distilled water was carried out for 14 days, at the end of which time the extract had lost a good proportion of its original activity.

After ascertaining that addition of  $\text{MgSO}_4$  to such a dialysed extract restored its activity, the optimum  $q_{\text{Mg}}$  [Jenner and Kay, 1931] was determined by carrying out activity determinations in the usual way except that a series of substrates was used, all of them  $M/100$  in disodium phenyl phosphate but containing  $\text{MgSO}_4$  in such concentrations as to give  $q_{\text{Mg}}$  values, when mixed with buffer and enzyme, ranging from 1.4 to 6.1.

Fig. 10 shows curves relating  $q_{\text{Mg}}$  with the experimentally found activities of a mammary gland extract at  $p_{\text{H}}$  10.0. All the curves exhibit optima at about  $q_{\text{Mg}}$  3 to which value approximate the optima found by Jenner and Kay [1931] for kidney phosphomonoesterase.

The activity of undialysed mammary gland extracts could be increased by addition of appropriate amounts of Mg salts but as the curve in Fig. 11 proves, such addition and the resulting enhanced activation are without effect on the optimum  $p_{\text{H}}$ .

In respect of Mg activation mammary gland phosphomonoesterase thus behaves qualitatively and quantitatively in a similar way to kidney phosphomonoesterase.

*Synthesis of sodium glycerophosphate by mammary gland phosphomonoesterase.*

The ability of the "alkaline" phosphomonoesterases of animal tissues to catalyse the synthesis of monoesters of orthophosphoric acid is well established, and it was therefore considered important to determine whether the mammary gland enzyme resembles the other tissue phosphomonoesterases in this respect. Tubes were set up each containing 5 ml. of active mammary gland extract, 5 ml. of 0.1  $M$  glycine buffer containing 0.119 g.  $\text{Na}_2\text{HPO}_4$  and 10 ml. of 90% glycerol. Controls were similar in every respect save that they contained boiled extract. Experiments were carried out in duplicate, using buffers at each of the  $p_{\text{H}}$  values ( $37^\circ$ ) shown in Table II. Electrometric  $p_{\text{H}}$  control measurements

Table II.

$p_{\text{H}}$ ...	...	8.2	8.5	8.9	9.3
% synthesis (active extract)		7.6	12.5	12.5	12.5
% synthesis (boiled extract)		0	0	0	0

were omitted in this instance since at the time these experiments were made a suitable apparatus was not available. The object of these experiments was merely to establish the fact that the phosphomonoesterase of mammary gland is able to catalyse the synthesis of glycerophosphate and accurate  $p_{\text{H}}$  control was therefore considered unnecessary.

The tubes were incubated at  $37^\circ$  and samples taken from each at intervals for the estimation of inorganic and total phosphorus. The amount of synthesis in each of the four series of experiments as measured by the decrease in inorganic phosphate after 172 hours at  $37^\circ$  is given in Table II.

The experiments show definite evidence that mammary gland phosphomonoesterase will catalyse the synthesis of glycerophosphate, its qualitative behaviour in this respect being similar to that of the kidney enzyme [Kay, 1928]. The synthetic activities of the mammary gland phosphomonoesterase are being further studied.

*Identity of the phosphomonoesterases of the mammary gland and kidney.*

Criteria for the identity of two enzymes from quite dissimilar tissues are not very precise. It is not without interest therefore to summarise the evidence of what seems to us to be a proven case of enzymic identity between the "alkaline" phosphomonoesterase of the mammary gland and that of the kidney.

(1) Each enzyme can be extracted from its respective tissue source by simple maceration of the tissue with sand and chloroform water preferably followed by 18–24 hours' autolysis at room temperature.

(2) The phosphomonoesterase from each source hydrolyses disodium phenyl phosphate optimally at  $p_H$  10.0 and in presence of 0.009  $M$  substrate.

(3) In the case of both enzymes the  $p_H$  optimum depends on the substrate concentration.

(4) The relation between substrate concentration and enzymic activity is in both cases identical. The behaviour of each enzyme agrees well with the Michaelis-Menten theory over the same limited range of substrate concentrations. At higher substrate concentrations both deviate similarly from the behaviour required by this theory. For both enzymes  $K_m = 0.0006$  at  $p_H$  10.0.

The substrate concentration-enzymic activity relation for each of these two enzymes agrees with the theory of Haldane which postulates competitive inhibition on the part of the substrate when the latter is in high concentrations. The constants in the Haldane equation are the same for both enzymes.

(5) Small concentrations of Mg salts activate both enzymes to a striking degree. The optimum  $q_{Mg}$  for dialysed extracts of both tissues is approximately 3.

(6) In the case of each enzyme optimum hydrolysis at a given temperature and when fully activated by Mg is defined by two conditions— $p_H$  and substrate concentration (for sodium phenyl phosphate,  $p_H$  10 and 0.009  $M$ ).

(7) Both phosphomonoesterases are rapidly inactivated at constant temperature both by  $H^+$  and  $OH^-$  ions and in a precisely similar way.

(8) The synthesis of glycerophosphoric acid from glycerol and disodium hydrogen phosphate is catalysed by each of the enzymes.

There is thus identity in every quality so far examined between the very active "alkaline" phosphomonoesterase of the mammary gland (whose net relevant activity, at least when functional, is, presumably, rapid synthesis of phosphoric esters) and that of the kidney (whose net relevant activity is either hydrolysis or nil).

## SUMMARY.

With an improved technique for the estimation of phosphatase activity, the "alkaline" phosphomonoesterase of the mammary gland has been closely examined. The optimum  $p_H$ , optimum substrate concentration, Michaelis constant and its variation with  $p_H$ , effect of Mg, inactivation by acid and alkali, synthetic activities all lead to the view that it is identical with the "alkaline" phosphomonoesterase of kidney tissue, and that despite its presence in a gland where phosphoric ester synthesis is rapidly proceeding, it appears to have synthetic powers which are no greater than those of other "alkaline" mammalian enzymes when examined under similar conditions.

Mammary tissue is noteworthy in its high content of phosphomonoesterase.

Our thanks are due to the Government Grant Committee of the Royal Society for a grant to one of us (S. J. F.) towards the cost of the apparatus used in this work.

# CCXVI. THE LEAD CONTENT OF HUMAN TISSUES AND EXCRETA.

BY SIDNEY LIONEL TOMPSETT AND ALAN BRUCE ANDERSON.

*From the Biochemical Laboratory, Department of Pathology of the University and Royal Infirmary, Glasgow.*

*(Received May 31st, 1935.)*

THAT lead is normally excreted in human urine and faeces is now well established. The literature has been reviewed by Kehoe *et al.* [1933, 1, 2], who have carried out an exhaustive study of the excretion of lead by normal American adults and children.

The occurrence of appreciable amounts of lead in "normal" human bones is also generally agreed upon, although there is considerable variation in the figures published, *e.g.* Barth [1931] finds 0.01-0.06 mg. Pb per g. ash or approximately 5-30 mg. Pb per kg. fresh bone, whilst Lynch *et al.* [1934] find 14-146 mg. Pb per kg. fresh bone. The position as regards the soft tissues is very unsatisfactory; few analyses are available and the evidence for the occurrence of "normal" lead in tissues is conflicting. Meillère [1903] states that small amounts of lead were present in the organs of nearly all the subjects examined by him (1-2 mg. per kg. on the average in the liver and spleen). Aub *et al.* [1926] state that the lead retained by an apparently normal individual is held almost exclusively by the skeleton. Weyrauch and Muller [1933] found no appreciable amount of lead in the liver, kidney, spleen or brain. Sheldon and Ramage [1931], using a spectrographic method, found lead occurring spasmodically in normal organs, whilst Boyd and De [1933], also using a spectrographic method, found lead well marked in the liver and present in all the other organs examined except the brain. Lynch *et al.* [1934] in an analysis of a few organs found 1.5 mg. per kg. in some livers and kidneys and none in others. Kehoe *et al.* [1933, 1] found appreciable amounts of lead in most of the tissues from two cases apparently normal shortly before death.

Whilst the estimation of lead in bones is comparatively easy, the soft tissues, having a high iron content and yielding only a small amount of ash, present considerable difficulties. It is probable that the differences in the published results may be attributed to the methods of analysis used, which are open to several criticisms. A number of methods have been used. Fairhall [1924] described a method in which the lead was precipitated as sulphide and then as the chromate. The lead chromate was determined either (1) colorimetrically with diphenylcarbazide or (2) by titration with thiosulphate after the addition of potassium iodide. Kehoe *et al.* [1926; 1933, 1, 2] used modifications of this method. Cooksey and Walton [1929], in an examination of urine, made a preliminary separation of lead by an electrolytic method. The lead was subsequently estimated nephelometrically as the sulphite. Francis *et al.* [1929] described a process involving the precipitation of lead as sulphide followed by electrolysis and precipitation as the sulphate. Finally the lead was estimated colorimetrically as the sulphide. Weyrauch and Muller [1933] and Litzner and Weyrauch [1932; 1933], investigating the distribution of lead in man, separated lead as the sulphide and then as the peroxide by electrolysis. They estimated the lead colorimetrically by

the blue colour formed by the interaction of the peroxide and tetramethyldiaminodiphenylmethane.

One of the major problems in the determination of lead is to separate it from substances that would interfere in the final stage of the estimation. The chief of these is iron. None of the above methods can claim to perform this process satisfactorily. Electrolytic methods usually fail in the presence of large amounts of iron [Francis *et al.*, 1929], while precipitation as lead sulphate or chromate is unsuitable as these substances have solubilities which are appreciable when fractions of a mg. of lead are being dealt with. In a recent paper [1935] Kehoe *et al.* acknowledge a loss of 0.07 mg. Pb per sample in the earlier method they employed.

A method suggested by Allport and Skrimshire [1932, 1] for separating lead from solutions of the ash of dyestuffs appeared to solve such difficulties. An alkaline solution of the ash was shaken up with a chloroform solution of diphenylthiocarbazone (dithizone). Lead was extracted by the chloroform as a lead-diphenylthiocarbazone complex. Iron was not extracted and other metals, with the exception of bismuth, were not extracted if cyanide were present. Under the latter conditions then, only two metals, lead and bismuth, were extracted. With this method it is recognised that certain difficulties are encountered. The aqueous solutions must be perfectly clear, the slightest turbidity due to phosphates, iron *etc.*, preventing a complete extraction of lead. As the extractions must be carried out on alkaline solutions, this is difficult, even when citrates have been added, for a solution may appear perfectly clear and yet iron, phosphates *etc.* may be precipitated in colloidal form and so prevent a complete extraction. The  $p_H$  of the solutions needs careful adjustment which is not always easy when certain classes of materials are being examined. If the organic matter has been destroyed by a wet oxidation method, the nature of the oxidant appears to exert a marked influence. Allport and Skrimshire [1932, 2] found that if nitric acid had been used as the oxidant, extraction of the lead was generally incomplete. This appears to be due to traces of oxidant remaining in the digest. We have found that in practice, when used to separate lead from solutions of the ash of urine, liver *etc.*, the method gave erratic results. In every case the solutions appeared perfectly clear.

In the final stage of the estimation of lead, the sulphide reaction appears to have been most commonly used. Unfortunately this is not specific for lead, bismuth giving a similar reaction. The sulphide reaction also lacks sensitivity. A more sensitive reaction is required for the determination of lead in blood, as the amount of blood that can be taken from a patient under routine conditions is limited. The objection to the tetramethyldiaminodiphenylmethane reaction is that although it is very sensitive, it is not specific for lead peroxide, substances such as manganese dioxide reacting similarly. Apart from the objections to electrolytic methods in general already referred to, manganese tends to be deposited as the dioxide along with lead. This is an especial failure of the method as manganese occurs in human tissues and excreta in appreciable amounts.

The present paper is divided into two parts. In the first a method for the estimation of lead, in which the difficulties outlined above have been overcome, is described. The second part deals with the lead content of human tissues obtained *post mortem*, and also the lead content of blood and excreta from hospital patients and normal individuals.

## I. THE METHOD FOR THE ESTIMATION OF LEAD.

By S. L. TOMPSETT.

*The separation of lead.* When an aqueous solution of sodium diethyldithiocarbamate is added to a solution of a copper salt a yellow organic copper complex is formed which may be extracted with ether. The extraction is complete in acid, neutral or alkaline solution, *i.e.* is independent of  $p_H$ , but is preferably carried out in alkaline solution in the presence of pyrophosphate to prevent the extraction of iron. The exact adjustment of  $p_H$  is unimportant [Tompsett, 1935].

Lead also was found to form an organic complex with sodium diethyldithiocarbamate, which could be extracted with ether. The lead complex is white and therefore ethereal extracts are colourless. Amounts of lead varying from 0.01 to 0.2 mg. could be extracted quantitatively by such a technique. The complex of lead and sodium diethyldithiocarbamate is very insoluble in water, turbidities appearing when the reagent is added to 0.05 mg. Pb or more in 100 ml. water. Sodium diethyldithiocarbamate itself is insoluble in ether, so that the amount of organic material extracted is minimum.

*The estimation of lead.* Fischer and Leopoldi [1934] have published a colorimetric method using diphenylthiocarbazone for the estimation of small amounts of lead. When an alkaline solution of a lead salt was shaken with a carbon tetrachloride solution of diphenylthiocarbazone, a pink complex with lead was formed, which was extracted by the organic solvent. After the shaking process, the carbon tetrachloride layer contained pink lead complex and also unchanged green diphenylthiocarbazone. Unchanged diphenylthiocarbazone was removed by repeatedly shaking the carbon tetrachloride with 1% KCN solution. Finally the pink extract was shaken with dilute acid, which changed the colour to green and then compared in a colorimeter with a standard. They stated that the method was quantitative and that amounts of lead of the order 6 to 120  $\gamma$  could be estimated, also that the reaction was specific for lead.

The writer has found that the pink colour is just as sensitive to colorimetric comparison as the green colour developed after shaking with acid. Using 10 ml.  $CCl_4$  to extract the complex it was found that the depth of colour was proportional to the Pb concentration within the range 5 to 70  $\gamma$ . The best depth of colour for colorimetric comparison appears to be in the region of 0.01 and 0.02 mg. Pb. With amounts of lead above 0.03 mg. the colour was too strong for colorimetric comparison.

*Reagents.*                      *The determination of lead in urine and faeces.*

- (1) Concentrated hydrochloric acid—analar reagent.
- (2) Concentrated nitric acid—analar reagent.
- (3) Perchloric acid—analar reagent.
- (4) Glacial acetic acid—analar reagent.
- (5) Ammonia (sp. gr. 0.88)—analar reagent.
- (6) Ether—analar reagent.
- (7) 10% potassium cyanide—PbT (B.D.H.). This was diluted 1 in 10 as required.
- (8) Carbon tetrachloride—analar reagent.
- (9) 5% sulphurous acid—lead-free.
- (10) 20% sodium citrate—lead-free.

A lead-free solution was prepared as follows. To 1 litre of a 20% solution in water, 100 ml. of 0.1% diphenylthiocarbazone in chloroform were added and

the mixture was shaken vigorously. As required, a small portion was passed through a filter-paper to remove suspended particles of chloroform.

(11) 0.1 % diphenylthiocarbazone in carbon tetrachloride.

Commercial diphenylthiocarbazone contains a yellow oxidation product which is soluble in carbon tetrachloride but is not extracted by alkali cyanide solutions. The commercial product was purified as follows. 100 ml. of 0.1 % diphenylthiocarbazone in carbon tetrachloride were extracted with several 100 ml. portions of 0.5 % ammonia. Diphenylthiocarbazone passes into the aqueous phase, leaving the oxidation product in the carbon tetrachloride. The ammoniacal extracts were passed through filter-paper to remove suspended particles of chloroform and then acidified with sulphurous acid. The green precipitated diphenylthiocarbazone was then extracted with 100 ml. of carbon tetrachloride. This solution if preserved under a layer of sulphurous acid (5 %) will keep indefinitely.

(12) 2 % sodium diethyldithiocarbamate.

Before use a small volume was shaken up with ether to remove traces of lead.

(13) Standard solution of lead acetate.

0.1831 g. of lead acetate  $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot 3\text{H}_2\text{O}$  was dissolved in distilled water containing 5 ml. of glacial acetic acid. The volume was then made up to 1 litre with distilled water. 1 ml. of this solution is equivalent to 0.1 mg. Pb. This solution was diluted as required so that 1 ml. was equivalent to 0.01 mg. Pb.

The water used was glass-distilled. Filter-papers were washed with dilute acid, followed by distilled water. Pyrex glassware was used. Silica dishes were always cleaned out with hot dilute acid prior to use.

*Method.* 500 ml. of urine were evaporated to dryness in a silica dish on a steam-bath and then ignited over a Bunsen burner in a fume cupboard. Final traces of carbon were removed by adding 5 ml. of concentrated nitric acid to the cooled ash and heating further.

The ash was dissolved in 100 ml. of water containing 5 ml. of concentrated HCl, and the solution transferred to a 750 ml. separating funnel. 100 ml. of 20 % sodium citrate solution were added and the mixture was made slightly alkaline to litmus by the addition of ammonia (sp. gr. 0.88). The volume of the solution at this stage should be about 400 to 500 ml. 10 ml. of sodium diethyldithiocarbamate solution were added followed by 25 ml. of ether. The mixture was shaken vigorously. The aqueous layer was run off and the ether extract washed twice with 25 ml. of water. The ether extract was run into a 300 ml. Kjeldahl flask, the separating funnel being rinsed with 10 ml. of ether. The aqueous solution and washings were extracted a second time with ether. The combined extracts were evaporated to dryness on a steam-bath and the organic matter was destroyed by heating with 1 ml. concentrated sulphuric acid and 1 ml. perchloric acid. After digestion fumes were removed by a water pump. The following were added to the digest in order: 10 ml. water, 1 ml. glacial acetic acid, and 5 ml. ammonia (sp. gr. 0.88) and the volume was made up to 25 ml. with water.

The final stage of the estimation was carried out as follows. Three glass-stoppered 50 ml. volumetric flasks were taken. 5–10 ml. of the diluted digest were measured into one of the flasks. Similar amounts of blank solution were measured into the other two flasks. The blank solution was prepared in exactly the same way as the unknown. For every 5 ml. solution in the flasks 6 drops of sulphurous acid were added. Into one of the blank flasks 1 or 2 ml. of standard lead acetate solution (equivalent to 0.01 or 0.02 mg. Pb), depending on the lead

content of the unknown, were measured. To each flask were now added 5 ml. 1 % KCN solution, 10 ml. carbon tetrachloride and 0.5 ml. 0.1 % diphenylthiocarbazone. After vigorous shaking the contents of the flasks were poured into test tubes and the aqueous layers removed with a teat pipette. After being returned to the flasks, excess diphenylthiocarbazone was removed from the carbon tetrachloride layers by repeated extraction with 10 ml. lots of 1 % KCN solution. Usually 4-6 extractions were necessary. The pink extracts were then washed with water and compared with a standard in a colorimeter.

After washing with distilled water the extracts were quite clear and did not require filtration. Filtration should be avoided as yellow tints tend to develop after the extracts have passed through filter-paper. After the diluted digest has been shaken with diphenylthiocarbazone, the aqueous layer should be coloured brown, indicating that excess of the reagent is present, otherwise more must be added. In the event of 5 ml. of diluted digest containing more than 0.03 mg. Pb, a smaller volume should be used which should be diluted to 5 ml. with blank solution. A blank was always done to control contaminations from outside sources. The blanks showed perceptible pink tinges but were too small to be measured. That the blanks showed a reaction at all is due to the extreme sensitivity of the test.

In the case of faeces, 5-10 g. of dried material were ignited in a silica dish and the estimation proceeded with as above.

From the results shown in Table I it will be seen that lead added to urine or faeces may be estimated quantitatively by the above method. The urine and faeces used in these recovery experiments were collected with no special precautions to exclude contamination. The figures therefore cannot justifiably be taken as representative of the lead content of urine and faeces in the normal subject.

Table I. *The recovery of lead added to urine and faeces.*

Urine. Volume used—500 ml.			Faeces. Weight of dried faeces used—10 g.		
Initial lead content mg.	Lead added mg.	Lead recovered mg.	Initial lead content mg.	Lead added mg.	Lead recovered mg.
1	0.063	0.100	8	0.143	0.500
2	0.053	0.050	9	0.104	0.500
3	0.025	0.100	10	0.100	0.500
4	0.063	0.200	11	0.048	0.400
5	0.062	0.100	12	0.167	0.250
6	0.031	0.100			
7	0.077	0.100			

The specimens of urine and faeces were collected with no special precautions to exclude contamination from outside sources. The results must not be taken as representative of the normal.

By the use of an ignition method for destroying organic matter, blanks have been reduced to a minimum. There were no losses observed when this method was applied in the estimation of lead in urine and faeces. This is probably due to the high ash content of these materials, much of which is in the form of phosphates. It was not necessary to add pyrophosphates to prevent extraction of iron in the preliminary separation of lead as they are formed in sufficient quantity during the ignition process.

In preliminary experiments the carbon tetrachloride extracts containing the lead diphenylthiocarbazone complex often had yellow tints which made colorimetry difficult. It was considered that this was due to traces of perchloric acid in the digests. The addition of 6 drops of sulphurous acid to every 5 ml. of

diluted digest used prevented the formation of this yellow colour and perfect matching colours could be obtained.

Although sodium diethyldithiocarbamate is not a specific reagent for the separation of lead, those metals that are extracted, *e.g.* copper, zinc, bismuth, do not interfere, as the complexes that they form with diphenylthiocarbazone are unstable in the presence of cyanide. The bismuth complex is orange-coloured and if present will be seen in the carbon tetrachloride layer after the first shaking. It is removed however during the subsequent extractions with cyanide. In actual experiment it was found that 0.01 mg. Pb could be estimated in the presence of 0.1 mg. Bi, the bismuth complex being completely removed at the fourth extraction. The complexes of the other metals are so unstable in the presence of cyanide that they are not formed at all.

The separation of lead as the complex with sodium diethyldithiocarbamate serves the very useful purpose of removing those substances such as iron and the phosphates of the alkaline earths which interfere with its reaction with diphenylthiocarbazone.

After extraction of the diethyldithiocarbamate complexes with ether, a few ml. of dilute copper sulphate solution should be added to the residual aqueous solution. The formation of a golden brown colour will indicate that excess of the diethyldithiocarbamate reagent has been added. In the majority of cases the amount of reagent indicated in this paper is in marked excess but in a few cases more may be necessary.

## II. THE LEAD CONTENT OF HUMAN TISSUES AND EXCRETA.

By S. L. TOMPSETT AND A. B. ANDERSON.

### EXPERIMENTAL.

*Urine and faeces.* The urine was collected in paraffined bottles and 500 ml. were taken for each estimation. The faeces were collected directly into large pyrex glass dishes in which they were dried. For each estimation 5–10 g. of dried and powdered material were used.

*Soft tissues.* The organs were first weighed and, except in the case of lung, 100 g. of tissue were chopped into small slices and placed in 100 ml. of lead-free 10% sodium phosphate solution in a silica dish. The whole right lung was first dried at 110° in a pyrex dish, ground to a powder and an aliquot portion of powder added to the phosphate solution in a silica dish. The mixture of tissue and phosphate solution was then evaporated to dryness on a steam-bath, and the subsequent procedure was the same as that described for urine and faeces. In the final colorimetric estimation 5–10 ml. of diluted digest were taken and compared with standards containing 0.01–0.02 mg. of lead.

*Bone.* About 5 g. of bone in small pieces were put into a silica dish without phosphate solution and ashed directly. The ash was treated in the same manner as that from other tissues.

*Blood.* Some modification of the method was necessary when dealing with blood owing to the smaller quantity of material used. The method is therefore given here in some detail. Approximately 20 ml. of blood were drawn from a vein with an all-glass syringe and stainless steel needle. Syringe and needles were sterilised by boiling in distilled water. The blood was immediately poured into a pyrex tube and rapidly pipetted into 100 ml. of lead-free 10% sodium phosphate solution in a silica dish. The exact volume of blood obtained was

noted. The contents of the dish were then evaporated to dryness on a steam bath and ashed in the same manner as the tissues, using only 1 ml. of nitric acid. The ash was dissolved in 50 ml. of water containing 2 ml. of concentrated HCl and the solution transferred to a separating funnel. The solution, which with the washings amounted to 100–150 ml., was made faintly alkaline to litmus by the addition of ammonia (sp. gr. 0.880), and cooled. After the addition of 2 ml. of 2% sodium diethyldithiocarbamate and 25 ml. of ether the mixture was shaken vigorously and allowed to separate and the aqueous layer run off. The ether extract was washed with 25 ml. of water and then run into a 150 ml. round-bottomed pyrex flask, a further 10 ml. of ether being used to wash the funnel. The aqueous solution was re-extracted with 10 ml. ether, which were added to the first extract, together with a second washing of 10 ml. of ether. The ether was then evaporated off on a steam-bath and the organic material in the residue destroyed by digestion with 0.2 ml. of sulphuric acid and 0.2 ml. of perchloric acid. The fumes were then removed from the flask by suction with a water pump, and 3.5 ml. water, 0.2 ml. glacial acetic acid and 1.0 ml. ammonia (sp. gr. 0.88) added in that order. After the addition of 6 drops of 5% sulphurous acid the contents of the digestion flask were transferred to a 50 ml. glass-stoppered pyrex volumetric flask and the digestion flask was washed out with 5 ml. of 1% KCN into the volumetric flask. To the mixture 10 ml. of carbon tetrachloride and 0.2 ml. diphenylthiocarbazone solution were added. The colour was then developed in the usual way and compared with a standard prepared similarly. For normal blood a standard containing 0.01 mg. Pb was found to be suitable when 20 ml. of blood were used. Sodium citrate was not added in the analysis of blood as any slight haze of calcium or magnesium phosphates did not interfere with the extraction.

Sodium phosphate was added to the blood and soft tissues before ashing for two reasons; firstly to increase the amount of ash and to prevent the formation of insoluble ferric oxide; secondly to form an excess of pyrophosphate which prevents the extraction of iron in the separation process. The sodium phosphate which was kept as a 10% stock solution was always de-leaded just before use in the following manner. To every 100 ml. of solution in a separating funnel 5 ml. of 2% sodium diethyldithiocarbamate solution were added and the whole was shaken vigorously with ether. The lead-free aqueous solution was then run off. The phosphate solution was not added to urine, faeces or bone, as these substances contain enough phosphate.

The results of analysis of organs from 22 *post mortems* are given in Table II, which is divided into 20 cases with no known occupational lead exposure and 2 cases with occupational exposure to lead, namely a painter and a printer. The figures are given for concentration in mg. Pb per kg. of fresh tissue and also for the total organ where possible. In the cases of rib and vertebra, concentrations alone are given. In order to obtain a representative sample of lung the whole organ was first dried and powdered as described above. For this reason only the total lead content of the lung is given. The cases in the first division range in age from 69 years to 6 weeks and consist of 11 males and 9 females. Lead in appreciable amounts was found in all the tissues examined, and with the exception of the spleen, the amounts present were remarkably constant considering the widely different pathological states involved. The figures for bone: rib, mean concentration 8.55 mg. per kg., and vertebra, mean concentration 7.09 mg. per kg., are the most constant, the greatest deviation from the mean being in the vertebra of No. 7 with a concentration of 14.7 mg., or just more than twice the mean value. The child of 2 years of age, No. 6, shows the

same concentrations of lead as the adults in liver, kidney, brain and bones. The spleen was not analysed. The figures for the 6-weeks old infant are remarkably high for some of the organs. The concentrations in the kidney and spleen of 3.55 and 3.08 mg. respectively are approximately twice the mean values for adults. The concentrations in the bones, 1.57 mg. for rib, and 2.6 for vertebra, are considerably less than the adult figures, as would be expected. The *post mortem* on this child showed a normal well-nourished baby and the organs, with the exception of the brain, were normal. Of the two cases with occupational exposure to lead, the painter shows an excessive deposition of lead in the bones; the concentration in the rib of 119 mg. is fourteen times the mean value, and that in the vertebra, 18.8, approximately two and a half times the mean. The printer shows a slight excess in the rib only. There is no suggestion of lead poisoning in the clinical notes on these two cases.

The tissues of four stillborn foetuses, two of which were twins, were also analysed, using the same method except that, in the case of the kidney, the modifications described for blood were used. For the analysis of bone, both femurs were used. The results are given in Table III. Lead was present in appreciable concentrations in all the tissues examined. The mean values for liver, kidney, and brain are from one-half to one-third of the adult values. The concentration in the femurs approximates to that found in the rib of the infant of 6 weeks. Of the twins, the female shows higher values than the male. For comparison, the copper in these tissues was determined at the same time; the mean values obtained were, in mg. per kg., liver—44.6, brain—1.08, and femur—1.86. These results show the usual selective absorption of copper by the foetal liver. The amount in the livers was at least five times that reported for the adult [Tompsett, 1935].

Urine and faeces were collected from three laboratory workers, as normals, and from ten hospital patients, in periods of two or three consecutive days. The normals were working and eating their ordinary diet. The patients, with the exception of No. 5 who was a case of pernicious anaemia, were in the metabolic wards for determination of basal metabolic rate, which in every case was within the normal limits. The diagnosis in most cases was tachycardia of unknown origin or "neurosis". The figures for the daily excretion of lead in the urine and faeces are given in Table IV. It will be seen that the normals excreted daily 0.16 to 0.03 mg. in the urine and 0.40 mg. Pb in the faeces. The patients' excretion in the urine varied from 0.07 to 0.025 mg., with a mean of 0.05 mg., and in the faeces from 0.26 to 0.20 mg., with a mean of 0.22. A half-day's diet as given in the metabolic ward was dried down in a pyrex dish, and on analysis by the method used for tissues gave 0.22 mg. Pb *per diem*. The hospital water was found to contain 0.03 mg. Pb per litre. Patients on this diet would appear to excrete a fairly constant amount of lead, and this amount is less than that

excreted by the normal laboratory workers. This difference can probably be accounted for by a greater intake of lead in the diet and drinking water of the normals. The occurrence of large amounts of bismuth in the faeces during bismuth medication will interfere with the lead estimation. The only remedy is to discontinue the bismuth, and analyse the faeces in a few days' time, when the small amounts of bismuth that may be present will not interfere, because the bismuth diphenylthiocarbazone complex is unstable when shaken with cyanide.

Table IV. *The excretion of lead in urine and faeces.*

Before estimating the lead in the blood some recoveries of lead added to blood and serum were undertaken to test the method as modified for the smaller quantities. As will be seen from the figures given in Table V, a good recovery of lead added to blood was obtained. It should be emphasised here that the figures for the lead content of blood in Table V have no significance because the blood was mixed and obtained from contaminated sources.

Blood was then collected from the same normals as before and from 18 hospital patients. Twenty-five samples in all were taken. The figures are given in Table VI. The patients were chosen from among those not acutely ill, and where no diagnosis is given it is to be understood that no physical signs of organic disease were present. The blood lead varied from 70 to 40  $\gamma$  per 100 ml., with a mean value of 55  $\gamma$ . The figures are given to the nearest 5  $\gamma$ . In the case of normal No. 3 several figures are given; these represent determinations done on blood collected on different days both before and after meals.

Of several cases of suspected lead poisoning investigated only one showed definite plumbism and this case is discussed here. The clinical history is briefly as follows. A young man of 30 years of age was admitted to the medical wards

Table V. *Recovery of lead added to serum and blood.*

complaining of severe pains in the stomach with vomiting of a week's duration. The pain had no relation to food and was not affected by food. His occupation was that of a solder-maker. In this trade, which he had followed all his adult life, he mixed molten lead, tin and other metals. The clinical findings were a moderate anaemia, blood count showed 3,000,000 red cells, and 40% haemoglobin, with some punctate basophilia, no wrist drop or other signs in the nervous system. There was a marked blue line round the gums. The stools contained blood. An X-ray of the stomach did not reveal any lesion.

24. iv. 35	240	—	—	—	—

The chemical investigation is summarised in Table VII. It will be seen that soon after admission the urinary and faecal excretion of lead was not higher than would be expected in a normal person. In this connection the intake of lead must also be considered. For the first few days he was on a milk diet and later was given a peptic ulcer diet. A sample of the latter diet was analysed and found to contain 0.13 mg. of lead per diem. This alkaline milky diet was probably increasing the storage of lead in his bones. The figures for urine show the importance of calculating the excretion per day and not relying on the amount per litre. In contrast to his excretion of lead the blood lead was high,

being at least twice the normal. On 21. ii. 35 medication with potassium iodide, 15 grains *per diem*, was started. Ten days afterwards blood lead and the excretion of lead were the same as before. He was now free from pain and was discharged and given the potassium iodide, which he continued to take until he was readmitted 4 weeks later to the metabolic ward complaining of sharp pains in the stomach. The potassium iodide was discontinued on admission, and blood taken the next day gave the surprisingly high figure of  $380\gamma$  Pb. He was on the ordinary ward diet, and a 3-day collection of excreta showed a normal urinary excretion but a faecal excretion about twice that of patients on the ward diet. The pain became less and less severe, and 10 days after admission his blood lead had fallen to  $240\gamma$ . The lead line had almost disappeared when he was readmitted.

This man had been subjected to a prolonged occupational exposure to lead, both as solid and vaporised, and must have had large deposits in his bones. His symptoms were of the gastro-intestinal type probably with intestinal ulceration giving blood in the stools. Though showing clinical signs of lead poisoning and having a high blood lead, he showed little increase in lead excretion. The results of administration of potassium iodide for a period of weeks were a return of the abdominal pain and an increase in the blood lead to nearly treble the original figure.

#### DISCUSSION.

The salient features of the analysis of "normal" soft tissues are the presence of lead in all the tissues examined, and the comparatively constant concentration for the adult irrespective of age, sex or cause of death. The presence of small quantities of lead in the soft tissues might be deduced from the fact that lead is a constant constituent of blood. It is not suggested, however, that lead is necessarily present in these concentrations in the normal during life. The changes in metabolism preceding death may bring about a mobilisation of lead from the deposits in the bones. Lead was found in the bones in amounts of the same order as those reported by Kehoe *et al.* [1933] and Barth [1931]. The figures show less variation from the mean than those for the soft tissues. Analysis of bones other than the ribs and vertebrae taken in this investigation would probably give different results. The higher figures reported by Lynch *et al.* [1934] were obtained in the analysis of the shaft of the femur principally.

Whilst our results for tissues may be taken as "normal" for cases in the Glasgow Royal Infirmary, it is possible that a similar investigation in another part of the country would reveal different "normals". This "normal" figure is of importance in the evaluation of results undertaken for toxicological purposes. Whilst lead was present in all the foetal tissues examined, the amounts present, which were of the same order as that in normal blood, do not indicate any selective absorption of this element in the foetus. By contrast, copper was concentrated in the foetal livers.

In any investigation of the excretion of lead, the important figures are those for the amount excreted over a given period of time. For this reason we have given all results for urine and faeces as mg. per day. In the case of urine the concentration of lead varies with the volume secreted, and results expressed in mg. per litre, which is the usual practice, may be misleading.

The estimation of blood lead described above has many advantages. It can be completed in 24 hours, and, as only 20 ml. of blood are required, it can be repeated several times on the same subject, if necessary. The lead content of the normal bloods examined showed only comparatively small variations and the

mean value of  $55\gamma$ /100 ml. agrees with that of  $60\gamma$  reported by Kehoe *et al.* [1935] for a group of medical students. On the other hand Litzner and Weyrauch [1933] consider that a figure above  $40\gamma$  indicates an increased lead absorption. The method used by Litzner and Weyrauch is open to several criticisms which have been mentioned already. The estimation of blood lead would appear to be a more satisfactory method of investigation than the determination of the excretion of lead, the significance of which is unavoidably obscured by the presence of unabsorbed lead in the faeces, where the greater excretion is to be expected. This is illustrated by the case of plumbism reported here.

Lead is normally considered to be an accidental body constituent, and the term "normal" has been decried on these grounds. When the general occurrence of lead in foodstuffs and its presence in the tissues generally are taken into account it seems more reasonable to describe lead as a normal constituent of the human body.

With the information at present available the results of analyses of tissues, blood and excreta only justify a statement as to whether normal or abnormal amounts of lead are present. The final diagnosis of lead poisoning is in the province of the clinician, who can correlate the clinical, haematological and chemical findings.

#### SUMMARY.

1. An accurate method has been described for the estimation of lead in human tissues, blood and excreta. After ashing, the lead was extracted with ether as a complex with sodium diethyldithiocarbamate. The lead in the ether extract, after destruction of the organic material, was determined colorimetrically with diphenylthiocarbazone.

2. Lead was found in all the tissues examined. The mean concentrations in mg. Pb per kg. for adults were: liver—1.73, kidney—1.34, spleen—1.68, brain—0.5, rib—8.55, vertebra—7.09. Tissues from a case of known exposure to lead showed higher figures, more especially the rib, with 119 mg. per kg.

3. Analysis of four foetuses of 7–8 months' gestation gave mean concentrations in mg. per kg. of: liver—0.68, kidney—0.63, brain—0.17, femur—1.73. Lead was found in all these tissues in each case.

4. Figures for the excretion of lead in urine and faeces by normal laboratory workers and hospital patients are given. The mean daily excretion of lead by 10 patients was 0.05 mg. for urine and 0.22 mg. for faeces.

5. The analysis of 25 samples of blood obtained from 3 normals, and 18 patients, none of whom were acutely ill, gave values of  $40$ – $70\gamma$  per 100 ml., with a mean value of  $55\gamma$ .

6. A case of plumbism in a solder-maker showing very high concentrations of blood lead is reported.

Our thanks are due to Dr Muir Crawford for permission to use the clinical notes on one of his cases, to Dr J. C. Middleton and other members of the staff of the Royal Infirmary for specimens from the wards and also to Dr Dugald Baird for arranging the supply of foetal material.

Part of the cost of this investigation was defrayed from a grant from the Rankin Fund of the University of Glasgow.

# CCXVII. THE OCCURRENCE OF CATARACT IN RATS FED ON DIETS DEFICIENT IN VITAMIN B<sub>2</sub>.

By MARGHERITA COTONIO BOURNE AND MAGNUS ALFRED PYKE.

*From the Department of Physiology and Biochemistry, University College,  
London.*

*(Received June 15th, 1935.)*

DAY *et al.* [1931] in America first reported that they had obtained cataract in albino rats by feeding a diet deficient in vitamin B<sub>2</sub>. The ration used was that of Sherman and Spohn [1923] which has been widely employed in work with this vitamin. Cataracts were produced in 92% of rats after an average period of 72 days.

The work was developed by Langston *et al.* [1933] and by Langston and Day [1933] who observed an equally high incidence of cataract in mice and in young wild gray rats deprived of vitamin B<sub>2</sub>. By feeding diets deficient in vitamin B<sub>2</sub> Day, Langston and Cosgrove [1934] obtained cataract in rats and chickens and Day [1934] reported cataract in rats, mice, chickens and monkeys. The importance of cataract as a symptom of vitamin B<sub>2</sub> deficiency was stressed by these authors.

Day and Langston [1934] published further evidence that in nearly all the cases examined rats receiving a diet free from vitamin B<sub>2</sub> developed cataract. They found that the appearance of cataract was delayed where small but insufficient amounts of vitamin B<sub>2</sub> were given; and the delayed appearance of cataract was correlated with the growth-rate data. It was concluded that cataract was probably a better criterion of vitamin B<sub>2</sub> deficiency than was dermatitis.

These observations are of great interest since they are related to the problem of the aetiology of cataract as well as to that of vitamin deficiency. It is important that it should be established beyond doubt whether or not degenerative changes in the eye-lens can be produced by the omission of a specific substance, such as a vitamin, from the diet. It is equally important from the point of view of vitamin studies to know if cataract, which can readily be observed, is in fact a consistent symptom of a vitamin deficiency. In addition a technique for producing cataract regularly in a laboratory animal by dietary control would prove most useful in further studies in the aetiology of cataract. For these reasons it was considered advisable to attempt to repeat the work of Day and his colleagues. Experiments were therefore undertaken in which diets deficient in vitamin B<sub>2</sub>, including the Sherman and Spohn [1923] diet as used by the American workers, were fed to rats and the eyes examined with an ophthalmoscope at weekly intervals. The results of these experiments form the subject of the present communication.

## EXPERIMENTAL.

Thirty-six young black and white rats of about 70 g. weight were obtained from a commercial source and kept in single cages with wire screen bottoms. The Sherman-Spohn [1923] diet was fed. This consists of alcohol-extracted caseinogen

18 %, Osborne and Mendel salt mixture 4 %, butter fat 8 %, cod-liver oil 2 % and maize starch 68 %. Vitamin B<sub>1</sub> is supplied in the form of an alcoholic extract of rice polishings which is evaporated on a portion of the starch and mixed with the remainder of the constituents.

In addition to the thirty-six test animals twelve control rats were given the deficient diet with a supplement of 1 ml. per day of a standard 50 % solution of alkaline-autoclaved marmite as a source of vitamin B<sub>2</sub>. The animals were weighed and their pupils dilated with atropine and the eyes examined with the ophthalmoscope at weekly intervals.

#### *Nature of the ocular symptoms.*

The ocular changes occurring in this type of cataract have been fully described by Day *et al.* [1931] and by Langston, Day and Cosgrove [1933]. The lesions observed by us conform to the description of these authors, but in our experiments the incidence of lens changes was much lower than that found by Day and his collaborators. The highest percentage of cataract obtained by us in any series of rats was 31, whereas the American workers repeatedly observed an incidence of above 90.

In those cases in which cataract did occur the progress of the lens changes, as observed with the ophthalmoscope, followed the course described by Langston, Day and Cosgrove [1933]. The first change noted was an irregularity of refraction manifested by the appearance of shadows in the clear substance of the lens. In a few cases striae were seen extending from the periphery to the nucleus of the lens. The lens gradually became more opaque and the red reflex from the retina could no longer be obtained; in the final stage development of the cataract progressed to maturity when the whole lens appeared milky white.

The most consistent ocular symptom was that of a superficial keratitis; inflammatory changes in the cornea were observed in 92-100 % of rats on the Sherman and Spohn diet. In nearly all cases this inflammatory condition cleared up as the experiment progressed leaving the cornea clear; in a few cases it reappeared for a second time. Vascularisation and residual scarring of the cornea were observed in a few cases.

#### *Skin symptoms.*

The skin symptoms observed were not strikingly specific in nature but appeared as a general unhealthy condition. Although dermatitis was occasionally symmetrical in distribution, this was by no means the rule. Soreness, stickiness and swelling of the eyelids were common and in many cases there was alopecia around the eyes. These symptoms appeared in an average length of time of 93 days. Alopecia and soreness on the abdomen were noted. Here the sores were usually along the mid-line and were possibly aggravated by the rat pressing on the rim of the food pot. Sores at the base of the tail, on the paws and on the throat or at the back of the neck were also noted. In the case of affected paws, the back of the digits was frequently red and inflamed. Generally, the most extensive sores appeared on the neck. On the ventral side moist, red inflammation was sometimes seen and on the dorsal side of the neck some animals developed large scabs which would later be cast off leaving a bald patch. After prolonged periods on the deficient diet the rats had a characteristically dried up, dusty appearance. The fur looked grayish; quite distinct from the sleek black and white of the control animals.

*Incidence of symptoms*

The incidence of eye symptoms and skin symptoms in the rats in this experiment is shown in Table I. It can be seen that whilst the incidence of cataract was 31 %, different forms of dermatitis appeared in 92 % of the animals.

Table I. *Incidence of ocular changes and dermatitis in rats on the vitamin B<sub>2</sub>-deficient diet of Sherman and Spohn.*

Symptom	Number of rats affected	Incidence %	Av. time of appearance (days)
1. Cataract	11	31	79
2. Keratitis	33	92	70
3. General dermatitis	33	92	92
(i) Affection of eyelids (bald, sore, sticky, swollen)	25	69	93
(ii) Abdomen sore or bald	13	36	79
(iii) Soreness or baldness at base of tail	11	31	115
(iv) Sore paws	9	25	85
(v) Sores on neck	5	14	77

The mortality of this batch of rats was exceedingly low. All the rats that failed to develop cataract lived for more than 88 days. The average survival of the rats that died without lens changes appearing was 135 days, while two animals were killed after 158 days and four after 179 days. Whilst the average time taken for the development of cataract, as shown in the table, was 79 days, the earliest case occurred in 56 days and the last in 123 days. No pathological symptoms occurred in the twelve control rats receiving autoclaved marmite.

*Growth.*

Although the appearance of dermatitis has generally been noticed in vitamin B<sub>2</sub> deficiency, the principal criterion of the absence of the vitamin is lack of growth. In the present case the typical flat growth curves associated with vitamin B<sub>2</sub> deficiency were obtained.

An analysis of the growth of thirty-four test rats and twelve controls is given in Table II.

Table II. *Maximum increase in weight of rats on the Sherman-Spohn vitamin B<sub>2</sub>-deficient diet.*

	Av. maximum growth g.	Av. time days	Av. growth per week to maximum weight g.
12 control rats receiving 1 ml. alk.-autoclaved marmite per day	146	135	6.5
11 rats developing cataract	38	73	3.6
23 rats not developing cataract	27	88	2.1

It can be seen that whilst the growth of all test rats on the diet was very slow, the animals developing cataract actually made better growth than the rats whose lenses showed no changes. In the case of 29 of the 35 test rats listed in the table the final weight was considerably lower than the maximum weight. Also, during the first three weeks, while the animals still had stored reserves of vitamin to draw upon, the rate of growth was greatest. If the growth during this preliminary period is subtracted from the total, the average maximum growth of all the test rats is 15.2 g. and the average maximum growth of the rats developing cataract is 17.5 g.

## EFFECT OF THE ADDITION OF CYSTINE ON THE INCIDENCE OF CATARACT.

The SH-containing compounds, such as glutathione and cysteine, are thought to be a part of the specialised respiration mechanism of the lens and recent work by Bourne and Young [1934] suggests that naphthalene cataract in rabbits may be due to the withdrawal of cysteine. Caseinogen which is the source of protein in the present diet contains only a small proportion of cystine and Day *et al.* [1934] stated that when egg white, which is a notoriously rich source, is substituted for caseinogen no cataract occurs. The following experiment was carried out in order to test whether the addition of cystine to the vitamin B<sub>2</sub>-deficient diet would prevent the appearance of cataract.

Twelve rats were given the Sherman-Spohn diet as previously described but with the addition of 1% of cystine. Two control rats were also given 1 ml. per day of alkaline-autoclaved marmite. A second batch of twenty-three rats was given the deficient diet as before with three rats receiving marmite as controls.

Since in the first experiment it had only been possible to obtain a 31% incidence of cataract this second experiment could, at best, only give the most tentative results owing to the comparatively small number of rats. In fact, of the twelve rats receiving the diet *plus* cystine none developed cataract. The best survival was 94 days and the average 59 days. Of the twenty-three rats on the Sherman-Spohn diet, two developed cataract.

A summary of the experiment is given in Table III.

Table III. *Effect of the addition of cystine to the Sherman-Spohn diet.*

Symptom	Av. time of first appearance (days)		Number of rats surviving		Proportion of survivors affected	
	Diet	Diet <i>plus</i> cystine	Diet	Diet <i>plus</i> cystine	Diet %	Diet <i>plus</i> cystine %
Cataract	72	—	9	6*	22	0
Keratitis	29	31	22	12	100	100
Affected eyelids	54	50	13	11	85	82
Skin sores or baldness	66	48	11	11	73	82
Dropped penis	33	28	22	12	50	58

\* Survived 72 days.

The mortality of the rats in this experiment was generally higher than before. The second section of Table III therefore gives the number of rats surviving after the average time of first appearance of each individual symptom, and the third section shows the incidence of each particular symptom among these surviving rats. Although 22% of the rats fed on the Sherman-Spohn diet and living for 72 days developed cataract, this proportion represents only two rats.

A summary of the growth data from this experiment is given in Table IV.

Table IV. *Growth of rats on the Sherman-Spohn diet with and without the addition of 1% of cystine.*

	Av. maximum growth g.	Av. time days	Av. growth per week to maximum weight g.
Controls	120	112	7.5
Diet: (i) cataract	2	32	0.4
(ii) others	2	27	0.5
Diet <i>plus</i> cystine	7	31	1.6

It can be seen that the growth of the test animals in this experiment was even less than before. This could be taken to indicate that their state of vitamin B<sub>2</sub> deficiency was more complete. Even so the incidence of cataract has dropped from 31 to 22 % on the unaltered Sherman-Spohn diet.

#### EFFECT OF MAIZE STARCH ON THE PRODUCTION OF CATARACT.

Previous to the present experiments a large number of rats had been kept on a diet deficient in vitamin B<sub>2</sub> without the development of cataract; the diet was that commonly employed in the laboratory at University College. It consisted of Glaxo "casein" 20 %, McCollum salt mixture 5 % and rice starch 75 %. To this ration daily additions of cod-liver oil and Peters's extract of yeast, to supply vitamins A, D and B<sub>1</sub>, were made.

Workers on vitamin B<sub>2</sub> deficiency have in the past suspected that maize contains a toxin which might play a part in the production of the deficiency symptoms. In order to test whether the difference in behaviour of rats on the University College diet and on that used by the American workers was due to the use of rice starch in the former diet in place of maize starch the following experiment was carried out.

Eleven rats were started on the Sherman-Spohn diet as before. Fourteen rats were given the University College diet made with rice starch in the usual way and eleven animals were given the University College diet in which maize starch had been substituted for rice starch. Each batch of rats was controlled with two animals to which autoclaved marmite was given.

The growth data for this experiment are shown in Table V.

Table V. *Growth of rats fed on three diets deficient in vitamin B<sub>2</sub>.*

	Av. maximum growth g.	Av. time days	Av. growth per week to maxi- mum weight g.
Controls	101	126	5.6
Sherman-Spohn Diet: (i) cataract	31	56	3.9
(ii) others	9	37	1.8
U.C.L. Diet: (i) cataract	14	63	1.6
(ii) others	22	70	2.2
Maize starch diet	21	61	2.4

From this table it can be seen that the average maximum growth on all three diets was negligible.

In this case, again, although the experiment was continued for 133 days, the incidence of cataract was very low. Of the total number of 36 animals on the three diets only two individuals developed cataract. One of these animals was receiving the Sherman-Spohn diet and one the University College diet. No cataract appeared in the rats receiving the maize starch diet. Results are set out in Table VI.

From this evidence, therefore, it appears that the maize starch plays no part in the production of cataract. On the contrary, those rats receiving the maize starch diet survived in better condition than did the animals on either of the other rations.

The last column of Table VI is of some interest. It was shown in Table V that no appreciable growth occurred on any of the diets. Thus, from the point of view of growth alone, each was equally deficient in vitamin B<sub>2</sub>. But as regards

Table VI. *Symptoms appearing in rats fed on three diets deficient in vitamin B<sub>2</sub>.*

Symptom	Av. time of first appearance			Number of rats surviving			Proportion of survivors affected		
	Sherman-Spohn diet days	U.C.L. diet days	Maize starch diet days	Sherman-Spohn diet	U.C. diet	Maize starch diet	Sherman-Spohn diet %	U.C. diet %	Maize starch diet %
Cataract	79	101	—	5	7	9*	20	14	0
Keratitis	32	58	87	11	11	9	100	55	89

Skin sores or baldness	81	44	103	4	13	9	100	15	22

\* Survived 100 days.

affected eyelids and skin sores, whilst the incidence on the practically identical U.C.L. and maize starch diets was 36, 27, 15 and 22 % respectively, the percentage on the American diet was 71 and 100 %. It therefore appears possible, either that the Sherman-Spohn diet is lacking in some additional factor, which may or may not be a part of the vitamin B<sub>2</sub> complex (since we must now accept the vitamin as such), or that the diet contains some toxic factor.

#### DISCUSSION.

The results obtained by us differ in two important respects from those reported by Day and his associates. First, whereas the American workers have obtained a very high incidence of cataract, 92–100 % of all rats fed on the Sherman and Spohn diet, the highest proportion found by us when the identical ration was fed was 31 %. Second, Day and his collaborators have found that the occurrence of cataract is a more consistent symptom of vitamin B<sub>2</sub> deficiency than dermatitis. This is not the case in our experiment where in rats on the Sherman and Spohn diet dermatitis appeared in from 73 to 100 % of cases while cataract occurred in only 20–31 %.

The consistency with which Day and his associates have been able to repeat their observations is impressive, and the evidence which they present is convincing. At the same time our own experiments and the experience of other workers show that it is possible for rats to survive for long periods on diets deficient in vitamin B<sub>2</sub> without developing cataract [*v. György*, 1935]. Our own experiments in which cataracts occurred irregularly and at best in only a small percentage of animals suggest that some dietary factor may be concerned, but it is at present unidentified and therefore cannot be controlled. Whether this factor is a part of the vitamin B<sub>2</sub> complex or whether it is some other substance cannot be decided without further investigation. The recent work on the separation of vitamin B<sub>2</sub> into flavin and a supplementary substance should facilitate the solution of this problem.

#### SUMMARY.

Experiments were undertaken in an effort to repeat the work of Day and his collaborators who found that a deficiency of vitamin B<sub>2</sub> regularly produced cataract in rats. The results were as follows:

(a) 31 % of 36 young rats fed on the Sherman-Spohn diet deficient in vitamin B<sub>2</sub> developed cataract in an average period of 79 days.

(b) 22 % of 9 rats surviving on the Sherman-Spohn diet developed cataract in an average period of 72 days. No cases of cataract occurred among 6 rats surviving for this length of time on the same diet to which 1 % of cystine had been added.

(c) The incidence of cataract among 5 surviving rats on the Sherman-Spohn diet was 20 % in 79 days; the incidence among 7 rats fed on a diet composed of caseinogen, salt mixture and rice starch was 14 % in 101 days; no cases of cataract occurred among 9 rats surviving for 100 days on a diet of caseinogen, salt mixture and maize starch.

Since the incidence of cataract in our experiments is relatively low and since it was found that numbers of rats could survive for long periods on diets deficient in vitamin B<sub>2</sub> without developing cataract, it is concluded that the relationship of cataract to vitamin B<sub>2</sub> deficiency still remains obscure. The results of our experiments suggest that some dietary factor may be concerned in the production of cataract, but whether this factor is the whole of the vitamin B<sub>2</sub> complex or some component of it, or whether it is some new and unrecognised substance is not yet established.

We are indebted to Prof. J. C. Drummond for his advice and encouragement during the progress of this work. One of us (M. C. B.) is grateful to the Medical Research Council for a grant and the other (M. A. P.) wishes to acknowledge the generosity of Messrs Vitamins Ltd, in giving him the opportunity of taking part in this investigation. We are indebted to Mr H. T. Fawns for the preparations of large quantities of pure cystine and for his generous assistance in other respects.

# CCXVIII. THE SYNTHESIS OF RESERVE CARBOHYDRATE BY YEAST.

## I. SYNTHESIS FROM GLUCOSE AND MALTOSÉ AND THE INFLUENCE OF PHOSPHATE THEREON.

By RACHEL ANNE McANALLY AND IDA SMEDLEY-MACLEAN.

*From the Biochemical Department, Lister Institute.*

*(Received June 6th, 1935.)*

IN the course of an investigation into the carbohydrate and fat metabolism of yeast, Smedley-MacLean and Hoffert [1923] showed that a mild ale yeast stored significantly larger quantities of carbohydrate when it was incubated in maltose solution than when incubated in solutions of glucose, fructose or sucrose of similar concentration. They concluded that maltose was directly assimilated by the yeast and built up into reserve carbohydrate and pointed out that this conclusion was in agreement with the generally accepted view that the maltose unit was present in the glycogen molecule [*cf.* Irvine, 1923]. Their data also indicated that the addition of alkali phosphates to the non-oxygenated carbohydrate solutions in which the yeast was incubated raised the total amount of carbohydrate stored by the yeast cell [1924].

We have now undertaken an analysis of the reserve carbohydrate stored by the yeast cell under different conditions with particular reference to the glycogen content.

The methods employed by various investigators for separating the carbohydrates of yeast are based either on Salkowski's method [1894] of extraction of the yeast with 2% KOH or on Pflüger's method for the estimation of liver glycogen in which 60% KOH solution is used for the extraction. By using dilute KOH, glycogen and yeast gum were obtained in solution, whilst with repeated use of strong KOH, these together with a further fraction of carbohydrate were dissolved. The latter according to Salkowski [1914] consists of the so-called erythrocellulose obtained by him in 1894 by autoclaving with water the residue after dilute KOH extraction. This substance was identical in properties with glycogen, gave only glucose on hydrolysis but had a lower specific rotation than glycogen,  $[\alpha]_D$  173.7°. Meigen and Spreng [1908] claimed that, after further purification, Salkowski's product had  $[\alpha]_D$  112°, and obtained a substance with the same rotation by extracting with 15% KOH the residue left after extracting the original yeast with 0.25% KOH. Daoud and Ling [1931], however, autoclaved with 2% KOH the residue after extraction with 2% KOH at normal pressure, thus obtaining only glycogen and yeast gum together with inorganic phosphate and silica. This latter method is stated to bring into solution some 50% more of this residue than did Salkowski's method of autoclaving with water. This fraction therefore probably contained a large part of the carbohydrate that Salkowski failed to dissolve, which gave mannose and glucose on hydrolysis and was named by him "achroocellulose".

## FORMATION OF POLYSACCHARIDES BY YEAST CELL 1873

It seems therefore that a portion of the carbohydrate of yeast is present as glycogen and yeast gum in soluble form whilst another portion is rendered soluble by the action of KOH, then appearing as glycogen and gum and possibly also some substance closely resembling glycogen. Whether the insolubility of the latter fraction is due to its condition in the cell, possibly to the polymerisation of the soluble molecules or to esterification with phosphoric and silicic acids as suggested by Daoud and Ling [1931], is not established, nor has the least soluble fraction been fully examined for other polysaccharides.

In our experiments, by one treatment of the yeast with 60% KOH, we obtained glycogen and yeast gum in solution and an insoluble solid residue. This latter, which though insoluble in water gave a red colour when treated directly with iodine, must correspond with the achroocellulose and erythrocellulose described by Salkowski and also with the esterified glycogen and yeast gum of Ling. We have referred to this fraction as yeast insoluble carbohydrate, thus making no assumptions as to its nature.

### METHOD OF EXPERIMENT.

The liquid yeast was filtered under diminished pressure and, after washing, 7 g. of the yeast were taken for analysis, of which 1 g. was used for the estimation of total carbohydrate, 1 g. for the determination of dry weight and 5 g. for the separation of the individual carbohydrates. Similar portions of 7 g. weight were added to the various media which were to be investigated. After incubation at 25° for the given period, generally 2 days, the yeast was filtered off, washed and the total amount from each medium weighed: one-seventh of the total was taken for estimation of the dry weight, one-seventh for determination of total carbohydrate and five-sevenths for separation of the individual carbohydrates. In some experiments, at the end of 2 days, a sample of the medium was withdrawn, the residual sugar estimated and the appropriate sugar added to bring up the sugar content to the original strength, the incubation being continued for another 48 hours. In other experiments, this process was repeated at the end of 4 days, so that the total time of incubation reached 6 days.

The solutions compared were 5% glucose and 5% maltose with and without the addition of 0.05%  $\text{PO}_4$ . The phosphate was added by introducing a suitable amount of a solution containing 1.4 g.  $\text{KH}_2\text{PO}_4$  and 4.9 g.  $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$  per 100 ml. It is important that the specimens of phosphate should be tested to see that they are free from any traces of fluoride.

*Total carbohydrate* was determined by boiling the yeast for 2 hours with  $N$  HCl solution and estimating the reducing carbohydrate in the filtrate by Bertrand's method. This method was used throughout for estimating reducing sugar, the result being calculated in all cases as glucose.

*Glycogen* was estimated by digesting the yeast with 60% KOH for 3 hours on the water-bath, diluting and making up to 70% alcohol as described by Mayer [1923]. After standing, the liquid was decanted and the precipitate filtered off, washed with alcohol and ether and digested with hot water, the washing being continued until the filtrate gave no red-brown colour with iodine. A solution was thus obtained, containing the glycogen and yeast gum, and a residue of insoluble carbohydrate. An aliquot part of the solution was used for the estimation of glycogen and gum: the rest was saturated with ammonium sulphate, thus precipitating the glycogen, which was filtered off, hydrolysed and estimated as reducing sugar in the hydrolysate. Insoluble carbohydrate in the residue was hydrolysed and similarly estimated. In all cases the carbohydrate was

## FORMATION OF POLYSACCHARIDES BY YEAST CELL 1875

hydrolysed by heating for 2 hours on the water-bath with *N* HCl, this method having been compared with the more usual one for the hydrolysis of glycogen with 2.2 % HCl for 3 hours and found to give the same results.

### RESULTS (Table I).

*Total carbohydrate.* The amount of carbohydrate stored was increased after incubation in the glucose solution but after incubation in maltose or in a glucose-phosphate medium this increase was approximately doubled. Addition of phosphate to the maltose medium caused a further increase of the total carbohydrate stored.

*Glycogen.* The glycogen showed more consistent variations with the differences in media than did the storage of the other carbohydrates. Glucose produced a definite increase in glycogen content compared with that of the original sample of yeast: where the same sample of yeast was used, incubation in glucose-phosphate medium always produced more glycogen than incubation in a pure glucose solution. The glycogen content of the yeast from the maltose medium was always very high; it far exceeded that from the glucose medium and generally, but not quite invariably, that from the glucose-phosphate solution.

Considerable variations were found in the power of the different samples of yeast used to form glycogen, although the yeast was obtained from the same brewery. Thus for several weeks samples would give relatively high storage followed by a period in which in all experiments relatively low storage was obtained. It is therefore important that corresponding experiments should be carried out with the same sample of yeast in the different media.

In the majority of the experiments where samples of yeast incubated in maltose and maltose-phosphate media were compared the glycogen content of the latter was the higher: the difference was however usually not so marked as that between the glycogen values of the yeast incubated respectively in glucose and in glucose-phosphate solutions, and in some cases the amount of glycogen from a maltose-phosphate medium was less than from a maltose medium.

*Insoluble yeast carbohydrate (so-called cellulose).* The content of insoluble carbohydrate was raised after incubation in either glucose or maltose solution. The maltose was perhaps slightly more efficient, but no such marked difference as occurs in the case of glycogen storage was observed. The addition of phosphate produced a definite increase in the amount of insoluble carbohydrate stored, the effect being somewhat greater when the phosphate was added to the glucose than to the maltose solution. On the whole the glucose-phosphate medium appeared to be the most favourable for the development of this fraction.

*Yeast gum.* This was estimated by subtracting the weight of glycogen from the total soluble carbohydrate present. In some cases it was confirmed by estimation of the gum by precipitating with Fehling's solution and hydrolysing. Here an increase appeared to have been obtained after incubation in all the carbohydrate media investigated except glucose; maltose and glucose-phosphate media were equally favourable. The maltose-phosphate medium was on the whole the best but the difference was not sufficiently striking to be regarded as significant. When the gum was estimated directly the differences in storage appeared to be even less marked.

### SUMMARY.

1. The addition of phosphate to glucose or maltose media caused increased storage of glycogen, yeast gum and yeast insoluble carbohydrate by the yeast cell

2. The glycogen stored by yeast incubated in a maltose medium far exceeded that stored when the yeast was incubated in a glucose medium and usually exceeded that stored in a glucose solution of like concentration to which phosphate had been added.

3. This appears to be the first recorded instance of a direct biological synthesis of glycogen from maltose.

## CCXIX. THE OXIDATION OF PHENYL DERIVATIVES OF FATTY ACIDS WITH HYDROGEN PEROXIDE IN THE PRESENCE OF COPPER.

By ROBERT OWEN JONES AND IDA SMEDLEY-MACLEAN.

*From the Biochemical Department, Lister Institute of Preventive Medicine.*

*(Received June 25th, 1935.)*

THE method and extent of the oxidation of the phenyl derivatives of the fatty acids *in vitro* is of especial interest since it is largely on the results of feeding experiments carried out with these acids that Knoop's theory of the  $\beta$ -oxidation of the fatty acids in the body has been built up. In the present investigation we examined the influence of a cupric salt on the oxidation of phenyl derivatives of the fatty acids by means of hydrogen peroxide: an excess of the hydrogen peroxide was run into the mixture of sodium salt of the phenyl-substituted fatty acid with a small proportion of cupric salt, as in the method already described for the oxidation of fatty acids [Smedley-MacLean and Pearce, 1934]. At 90° the phenyl derivatives were much more rapidly attacked than the fatty acids themselves and it was found that even at 60° in less than an hour the acid in some cases was almost entirely converted into carbon dioxide: no attempt was made to keep either the concentration of the peroxide or the  $p_H$  constant.

The results of the oxidation of the fatty acids under parallel conditions are also given in Table I. In the absence of copper benzoic acid was almost unattacked at 60°, formic being rather better oxidised: propionic and butyric acids were almost unattacked; in the aromatic acids the extent of the oxidation increased with the length of the side-chain.

The addition of the cupric salt increased the amount of oxidation in all cases but most markedly in the aromatic series: formic and benzoic acids were readily attacked but the most vigorous action occurred with phenylacetic acid, for in less than half an hour 80% of this acid was oxidised to  $CO_2$ . A few minutes after the reacting substances were mixed together there was a rush of carbonic acid through the absorption apparatus, the effect being most striking when the peroxide and sodium phenylacetate were heated at 60° and the cupric salt solution then run in. The special susceptibility of phenylacetic acid to oxidation is possibly due to the fact that  $\beta$ -oxidation would take place at the nuclear carbon atom to which the side-chain is attached.

Both in the presence and absence of the catalyst, the unsaturated cinnamic acid was less readily oxidised than phenylpropionic acid.

In order to throw some light on the intermediate stages of the reaction, a series of experiments was carried out in which only limited amounts of hydrogen peroxide were added: at the end of the hour's heating, the residual solutions gave positive tests for the presence of phenolic compounds: qualitative tests with solutions of ferric chloride, silver nitrate, potassium cyanide, alkali and gelatin demonstrated the presence of polyhydroxy-compounds amongst which gallic acid was positively identified. The carbon content of the organic matter extracted by ether from the residual solution was 51.6%, theory for gallic acid requiring 49.4%.

Table I.

*Oxidation of aliphatic acids and phenyl-substituted fatty acids with hydrogen peroxide at 60° for one hour (A) without a catalyst, (B) with a copper catalyst.*

‡ Acetone.

Dakin and Herter [1907] showed that by the oxidation of phenylalanine with hydrogen peroxide hydroxy-groups were introduced into the aromatic nucleus and that the action of hydrogen peroxide on benzoic acid resulted in the formation of salicylic acid with smaller quantities of *m*- and *p*-hydroxybenzoic acids. There was also evidence of the presence of dihydroxy-compounds. Indications were obtained that the reaction proceeded to some extent at laboratory temperature, but in the actual experiments described the reaction mixture was heated for some hours at 100°.  $\beta$ -Phenylpropionic acid yielded  $\beta$ -phenylhydroxypropionic acid, acetophenone being also identified.

Traube [1910] showed that polyhydroxy-aliphatic compounds were oxidised by hydrogen peroxide in the presence of copper, a complex cupric ion being formed. Since hydroxylation of the nucleus occurred in the absence of copper the cupric salt probably reacts with the phenolic groups, as Weinland and Walter [1923] have shown happens in the case of catechol, and exercises a potent effect on the disruption of the benzene nucleus. That, in the presence of copper, it is the nucleus which is the chief point of attack seems also indicated by the fact that the oxidation is less potent with increasing length of side-chain, whereas in the absence of copper the reverse effect occurs.

The formation of succinic acid from phenylpropionic and phenylbutyric acids would indicate that oxidation had taken place in the  $\gamma$ -position. No evidence of the presence of any ketone was obtained. As in the case of the fatty acids [Smedley-MacLean and Pearce, 1934] the introduction of the cupric salt led to the formation of hydroxy- and not of keto-compounds.

Salkowski [1879] showed that phenylacetic acid was not oxidised in the organism but was excreted as phenylaceturic acid, whereas phenylpropionic acid was oxidised to benzoic acid and then eliminated as hippuric acid. Knoop [1904] extended this work and showed that when the phenyl derivatives of the fatty acids were fed to dogs, if the acid contained an even number of carbon atoms in the side-chain, phenylacetic acid appeared in the urine; if the side-chain contained an odd number of carbon atoms benzoic acid was eliminated, both the phenylacetic and benzoic acids being coupled with glycine. Quick's results [1926] make it probable that these acids are almost entirely eliminated either in combination with glycine or glycuronic acids. Dakin [1908] tested the hypothesis that the resistance of these acids to oxidation in the organism might be due to the protective action of the coupling with glycine: he carried out feeding experiments in which phenylpropionylglycine was fed: no quantitative data are given but the normal oxidation products of the uncoupled acid were detected in the urine, amongst them cinnamoylglycine. Since in the body however the coupling either does not take place or does not become protective until the stage of benzoic or phenylacetic acid has been reached, we carried out experiments to ascertain whether coupling with glycine affected the oxidation of these acids with hydrogen peroxide in the presence of copper and found that a marked degree of protection was accorded. The results are recorded in Table II.

Table II. *Percentage of carbon evolved as carbon dioxide during oxidations by means of hydrogen peroxide for one hour at 60° with a copper catalyst.*

	Experimental value	If coupled compound behaves as a mixture		Experimental value
Acetic acid	31.3	38.2	Aceturic acid	15.3
Glycine	45.2			
Benzoic acid	63.6	59.0	Hippuric acid	0.2
Glycine	45.2			
Phenylacetic acid	77.4	70.7	Phenylaceturic acid	39.0
Glycine	45.2			

We know nothing as to how this coupling is effected in the body, but the fact that coupling with glycine almost entirely prevents the oxidation of benzoic acid by hydrogen peroxide in the presence of a copper catalyst would support the view that the coupling acts as a protective mechanism.

#### SUMMARY.

1.  $H_2O_2$  in the presence of a cupric catalyst rapidly oxidised the phenyl derivatives of the fatty acids, phenolic compounds being formed as intermediate stages.

2. In the absence of the catalyst, with increasing length of side-chain, more of the acid was oxidised; in its presence phenylacetic acid was most readily attacked, 80 % of its carbon being converted into  $CO_2$  in less than half an hour at 60°.

3. Coupling with glycine rendered acetic, benzoic and phenylacetic acids less susceptible to oxidation, hippuric acid being practically unattacked under the conditions of oxidation used.

# CCXX. ABSORPTION SPECTRA OF THE METABOLIC ACIDS OF *PENICILLIUM CHARLESII* AND THEIR RELATIONSHIP TO THE ABSORPTION SPECTRUM OF ASCORBIC ACID.

BY REGINALD WILLIAM HERBERT AND  
EDMUND LANGLEY HIRST.

*From the Chemical Laboratories, University of Birmingham.*

(Received June 16th, 1935.)

It has been shown [Clutterbuck *et al.*, 1934] that *Penicillium Charlesii* G. Smith produces from glucose a polygalactose, a polymannose and a variety of metabolic acids. Evidence concerning the structure of the acids has recently been published by Clutterbuck *et al.* [1935, 1, 2]. Simultaneously with the work there recorded investigations of the absorption spectra of these substances were carried out in this laboratory with the idea that correlation of the data with the results of chemical transformations would be of assistance in the allocation of structural formulae. The present paper deals with the absorption spectra of carlic, carolic, carolinic and carlosic and other acids from the point of view of structural relationships and it will be seen that the observations now recorded give strong support to the constitutional formulae advocated by Clutterbuck *et al.* [1935, 1, 2].

Since  $\alpha$ -ethyltetronic acid (I,  $R_1 = \text{Et}$ ;  $R_2 = \text{H}$ ) and  $\alpha$ -acetyltetronic acid (II,  $R_1 = \text{CH}_3$ ;  $R_2 = \text{H}$ ) occupy special positions as reference substances in connection with the subject matter of this paper their absorption spectra will be

I

II

III

considered first. Aqueous solutions of  $\alpha$ -ethyltetronic acid are characterised by a single intense band with head at  $\lambda 258m\mu$ , the corresponding value of the molecular extinction coefficient ( $\epsilon_{\text{max.}}$ ) being 12,000. In acidified aqueous solutions the values are  $\lambda 233m\mu$ , and  $\epsilon_{\text{max.}}$  12,000 respectively, but in alkaline solutions the head of the band is at  $\lambda 258m\mu$  and the value of  $\epsilon_{\text{max.}}$  is 18,000. This behaviour resembles very closely that of ascorbic acid (III) which has a single band at  $\lambda 265m\mu$  in alkaline solution and at  $\lambda 245m\mu$  in acidified aqueous solution (non-ionised condition) [Herbert *et al.*, 1933; Baird *et al.*, 1934]. Reference to the formulae shows a close structural similarity between the two substances

and ascorbic acid is in fact an example of formula I with  $R_1 = \text{OH}$  and  $R_2 = -\text{CHOH}.\text{CH}_2\text{OH}$ . Both ascorbic acid and ethyltetronic acid possess a lactonic CO group forming part of a system of conjugated double bonds to which the observed absorption is attributable. There is however one point of difference sufficiently noteworthy to require further comment. The  $-\text{C}(\text{OH})=\text{C}(\text{R})-$  group in  $\alpha$ -ethyltetronic acid is much less sensitive to oxidation in alkaline solution than is the corresponding dienol group of ascorbic acid. For this reason the absorption of the ionised form of  $\alpha$ -ethyltetronic acid is readily ascertainable but special precautions are necessary when solutions containing ionised ascorbic acid are under examination. For example when the absorption in pure water is being measured it is important to exclude all traces of metallic catalysts [cf. Mawson, 1935; Zilva, 1935]. Owing to the intensity of the band the aqueous solutions generally used for absorption work are excessively dilute (about  $M/10,000$ ) and under these conditions ascorbic acid (for which  $\log K = -4.1$ ) is mainly but not entirely in the ionised state. The absorption spectrum is therefore composite and the full intensity of the band at  $\lambda 265m\mu$  characteristic of the ionised acid is not developed. The absorption at  $\lambda 245m\mu$  is not sufficiently intense to be observed as a band and the main feature is the band at  $\lambda 265$  which has  $\epsilon_{\text{max.}}$  10,000. If to such a solution having  $\epsilon_{\text{max.}}$  10,000 acetate buffer containing a trace of potassium cyanide ( $M/1000$ ) is added to bring the  $p_{\text{H}}$  to 5 the ascorbic acid becomes completely ionised,  $\lambda_{\text{max.}}$  remains at  $265m\mu$  and the value of  $\epsilon_{\text{max.}}$  rises to 13,000. It is of course possible that in addition to ionisation other changes in the molecule affecting absorption may be promoted by the alteration from acid to alkaline conditions, but it is important to note that oxidation is not responsible for the lower value in water as compared with that in the acetate buffer [cf. Robertson, 1934]. In accordance with expectation concentrated aqueous solutions of ascorbic acid ( $N/10$ ), which have a lower  $p_{\text{H}}$  value, display the absorption band ( $\lambda_{\text{max.}}$   $245m\mu$ ) of the non-ionised acid [Herbert, Hirst and Wood, 1933]. Numerous synthetic analogues of ascorbic acid, many of which are entirely devoid of antiscorbutic activity display similar absorption bands and it will be shown below that all the natural products referred to in this paper possess bands in close proximity to that of *l*-ascorbic acid (vitamin C). For these reasons it is obvious that spectrophotometric methods for the assay of vitamin C should be used only with great caution.

The transition from  $\alpha$ -ethyltetronic acid to  $\alpha$ -acetyltetronic acid (II,  $R_1 = \text{CH}_3$ ;  $R_2 = \text{H}$ ) involves the addition of another unsaturated grouping to the molecule and a complex system of conjugated double linkages results. The absorptive power is thereby profoundly modified and is now characterised by two intense bands<sup>1</sup> situated respectively at  $\lambda 265m\mu$  and at  $\lambda 230m\mu$  the value of  $\epsilon_{\text{max.}}$  being 15,000 for both. A further difference is that there is now no appreciable change in the wave-length at the heads of the bands when aqueous acid or aqueous alkaline solutions are used in place of solutions in pure water.

The following four metabolic acids of *P. Charlesii*, carlic, carolic, carolinic and carlosic acids, display in aqueous solution absorption spectra characterised by two strong bands, the positions and intensities of which offer the closest possible parallel with the corresponding data for  $\alpha$ -acetyltetronic acid. Furthermore on reduction these acids give, by replacement of one oxygen by two hydrogen atoms, tetrahydro-derivatives which show single banded absorption spectra, the position and intensity of this band being closely similar to those of  $\alpha$ -ethyltetronic acid. The absorption data therefore suggest strongly that in aqueous

<sup>1</sup> It is not possible, from the data available, to apportion the contributions of the various groupings to these two bands.

solution these four acids possess markedly similar structures and that they are related to their tetrahydro-derivatives in the same manner as acetyltetronic acid is related to  $\alpha$ -ethyltetronic acid. In conjunction with the chemical evidence put forward by Clutterbuck *et al.* these results provide strong evidence in favour of the formulation of the four substances as the following derivatives of acetyltetronic acid (formula II):

Substance	$R_1$	$R_2$
Carolinic acid	$-(CH_2)_2 \cdot COOH$	$-CH_3$
Carlosic acid	$-(CH_2)_2 \cdot CH_3$	$-CH_2 \cdot COOH$
Carolic acid*	$-(CH_2)_2 \cdot CH_2OH$	$-CH_3$
Carlic acid*	$-(CH_2)_2 \cdot CH_2OH$	$-CH_2 \cdot COOH$

\* Hydrated form.

The tetrahydro-derivatives are derived from formula I in the following way.

Substance	$R_1$	$R_2$
Tetrahydrocarolinic acid	$-(CH_2)_3 \cdot COOH$	$-CH_3$
Tetrahydrocarlosic acid	$-(CH_2)_3 \cdot CH_3$	$-CH_2 \cdot COOH$
Tetrahydrocarolic acid	$-(CH_2)_3 \cdot CH_2OH$	$-CH_3$
Tetrahydrocarlic acid	$-(CH_2)_3 \cdot CH_2OH$	$-CH_2 \cdot COOH$

These four acids are separated into two distinct groups by virtue of important differences in behaviour between carolinic and carlosic acids on the one hand and carolic and carlic acids on the other hand. Whereas carolinic and carlosic acids display normal properties and have similar absorption spectra in aqueous and non-aqueous solvents, carlic and carolic acids crystallise with one molecule of water less than is represented by the above formulae and the anhydro-acids contain no appreciable active hydrogen (hydroxyl groups) when tested in anisole by the Zerewitinow method. The crystalline acids dissolve in water giving the hydrated forms indicated above, but the anhydrous forms of carolic acid and carlic acid have polycyclic structures. For suggestions concerning the nature of these ring systems the paper by Clutterbuck *et al.* [1935, 2] should be consulted. It suffices to say here that examination of the absorption spectra has revealed that in a non-aqueous medium (dry alcohol) both carolic and carlic acids display a single absorption band ( $\lambda 270-272 m\mu$ ) in place of the two well marked bands found in aqueous solutions. Strong indications are thus afforded of a difference in structure between the hydrated and non-hydrated forms and the close resemblance in the behaviours of carolic and carlic acids points to the operation of similar causes in both cases. In this respect the correlation of the chemical evidence with the absorption data presents difficulties in view of the structural differences between the formulae for carlic and carolic acids suggested by Clutterbuck *et al.*

The series of observations was extended by the investigation of various structurally related acids, of which *l*- $\gamma$ -methyltetronic acid ( $I$ ,  $R_1 = H$ ;  $R_2 = Me$ ) is a metabolic product of *P. Charlesii*. Its absorption falls exactly into line with others of this general type. Another example is  $\gamma$ -carboxymethyltetronic acid ( $I$ ,  $R_1 = H$ ;  $R_2 = CH_2 \cdot COOH$ ) which has a similar absorption spectrum. In addition two other acids of this series were encountered by Clutterbuck *et al.* [1935, 3], namely, ramigenic acid and verticillic acid which have been shown by these authors to be products derived by the condensation of *l*- $\gamma$ -methyltetronic acid with acetone. The absorption spectra are characterised by a single band with high values of  $\epsilon_{max}$ , corresponding with the high molecular weight and the number of absorbing centres of the tetronic acid type present in the molecule.

*Details of absorption spectra.*

The measurements were made with solutions containing about 2 mg. of the substance under examination in 100 ml. of solution. The figures given in Table I are molecular extinction coefficients, calculated from the expression  $\log I_0/I = \epsilon lc$  where  $c$  is the concentration in terms of g. mols. per litre. Figs. 1 and 2 show

Table I. *In water.*

interest, namely, the values of  $\lambda$  and  $\epsilon$  at the maximum and minimum points on the curves. These are given in Tables I–IV. It should be noted that the tendency, shown by curve II on Fig. 1, to broaden out towards the base is apparent even more markedly with aqueous solutions of other substances of formula I. This is

almost certainly due to the presence in the aqueous solution of a small proportion of the substance in the form which gives the band shown in curve III (see remarks above on the absorption spectra of ascorbic acid). The figures for carlic and carolic acids in Tables I-IV are based on the formulae  $C_{10}H_{10}O_6$  and  $C_9H_{10}O_4$  respectively (anhydrous forms).

#### SUMMARY.

1. The absorption spectra of carolinic, carlosic, carolic and carlic acids (produced by the action of *Penicillium Charlesii* G. Smith on glucose) have been investigated under a variety of conditions.

2. It is shown that the absorption spectra of the four acids show the closest possible similarity with that of  $\alpha$ -acetyltetronic acid and that the absorption spectra of the reduced acids resemble those of  $\alpha$ -ethyltetronic acid, *l*- $\gamma$ -methyltetronic acid and *l*- $\gamma$ -carboxymethyltetronic acid.

3. In dry alcohol carolic and carlic acids show an absorption spectrum different from that given by the hydrated acids in water.

4. It is shown that the absorption data can be correlated with the chemical properties of the substances and the observations are discussed from the point of view of structural relationships.

5. All the above substances are closely related to ascorbic acid and the bearing of the results on the use of the spectrographic method for the estimation of vitamin C is discussed.

# CCXXI. OBSERVATIONS ON THE BLOOD FATS IN DIABETIC LIPAEMIA.

By FREDA KATHARINE HERBERT.

*From the Pathological Department of the University of Durham College of  
Medicine and the Royal Victoria Infirmary, Newcastle-upon-Tyne.*

*(Received June 18th, 1935.)*

THE present study is concerned with two cases of diabetes mellitus with intense lipaemia. At the height of the lipaemia, the plasma fat ranged from 9 to 22 %, and these extraordinarily high values made it possible to extract and analyse the fat by large-scale methods. Such opportunities rarely occur, and it seemed worth while to study the composition of the fat, and in particular, to determine the iodine value of the separated fatty acids in the hope of obtaining some information as to the source of the fat in diabetic lipaemia. Comparisons were made between the fats of the food and those of the blood, but as the lipaemia diminished very quickly under treatment, these experiments were made during the period of recovery and not at the height of the lipaemia.

## *Methods.*

*Extraction and estimation of total fat.* A measured volume of plasma was diluted to 20 ml. with water, and an equal volume of alcohol was added. This was extracted with a mixture of equal parts of ether and light petroleum. The ether-petroleum layer was separated, the extraction was repeated twice more, and the extracts were combined. The solvent was removed by distillation followed by storage of the residue in a vacuum desiccator until constant weight was reached. The total fat was calculated from the weight of this extract.

*Saponification and separation of fatty acids and unsaponifiable matter.* A weighed amount of the extracted fat (usually 0.2–0.6 g.) was dissolved in neutral alcohol. An attempt was made to titrate any free fatty acid in this solution, but none was found. The material was saponified by heating with alcoholic potash under a reflux condenser ( $\frac{3}{4}$ –4 hours) and the saponification value was estimated by titration of the excess KOH. The solution containing the soap and unsaponifiable matter was concentrated and transferred to a separating funnel, using alternately water and alcohol, so that after complete transference the mixture contained approximately equal parts of water and alcohol. The unsaponifiable matter was removed by three successive extractions with a mixture of equal parts of ether and light petroleum. The combined solution containing the unsaponifiable matter was washed by shaking with water, the aqueous washings being added to the main solution of soaps. The solvent was removed from the unsaponifiable matter and the extract weighed.

The alcohol-water solution containing the soaps was next acidified, and the fatty acids extracted three times with ether and petroleum. The combined solutions were washed with water, the solvent was removed and the extract weighed.

**Cholesterol.** For the majority of analyses the colorimetric method of Myers and Wardell<sup>1</sup> [1918] was used. In some instances the results were confirmed by the digitonin method as used by Gardner and Gainsborough [1927].

**Lipin phosphorus.** A known amount of the fat was digested by heating with sulphuric acid and hydrogen peroxide (perhydrol), the peroxide being added cautiously in successive small amounts until the digestion was complete. The resulting solution was diluted and treated with an excess of sodium hydroxide. The solution was evaporated to dryness and the residue ignited. The final residue was dissolved in water and the phosphorus was estimated colorimetrically by the method of Kuttner and Cohen [Kuttner and Lichtenstein, 1930].

**Iodine values** were determined by the method of Wijs.

### *Clinical and experimental notes.*

**Case 1.** R. W., male, age 25, was admitted to the Newcastle General Hospital in March 1934. He had been treated for diabetes for 6 months with insulin and dietetic measures, but shortly before admission had indulged in large amounts of carbohydrate. No unusual amount of fat was taken. On admission, he had glycosuria and intense ketonuria, and the fasting blood sugar was 0.312%. The whole blood was the colour of chocolate. The plasma separated quickly and had the appearance and consistency of cream. The plasma fat was 22% and the cholesterol 1.41% (Table I). Under

treatment by diet and insulin the lipaemia and the hyperglycaemia were controlled. During the period of recovery a special diet was given in order to compare the fats of the food with those of the blood. This was started on Aug. 7th and continued until Aug. 14th, two blood samples being taken during this time (Table I). During the same period the average daily excretion of fat in the faeces was 5.5 g. The experimental diet contained 55 g. protein, 129 g. carbohydrate and 106 g. fat daily. Of the fat, 84 g. were given as butter, 18 g. were derived from eggs and the remainder from vegetable sources. The butter was analysed; the daily ration would yield 80 g. fatty acids of i.v. 39.1. The eggs were not analysed, but on the basis of figures given by Needham [1931] it was calculated that the daily ration of eggs would yield 15 g. fatty acids of mean i.v. 70. The mean i.v. of the fatty acids in the food would be 44.

The patient recovered and was discharged when a proper balance of diet and insulin had been established.

<sup>1</sup> It was noted that the rate of colour development was sometimes more rapid in the chloroform solutions of blood-fat than in pure cholesterol solutions. Erroneous results were obtained if the estimations were made after 10 minutes' colour development. At 15 minutes the colour was maximum in both the "standard" and "unknown" solutions provided that the solutions were perfectly free from moisture.

In the following August he again took excessive carbohydrate, but no undue amount of fat, and was re-admitted to hospital in coma with severe ketosis and a fasting blood sugar of 0.562%. There was lipaemia again, the plasma fat being 9.12% and the cholesterol 1.1% (Table II). For the first 4 days he was treated with insulin and glucose, and as soon as he began to take food he was given the same experimental diet as had been used before. This was continued throughout the period of the analyses given in Table II, except for an interval between August 7th and 10th when some bacon fat was given instead of butter.

Again, the condition was controlled by treatment and the lipaemia diminished. The patient was discharged on a balanced régime of diet and insulin.

In March 1935 another breach of diet was followed by coma. A blood sample taken during recovery under treatment with glucose and insulin showed only faintly turbid plasma and the cholesterol was 0.349%.

Case 2.<sup>1</sup> K. U., male, aged 9 years, was admitted to the Royal Victoria Infirmary in June 1934. He had been treated for diabetes mellitus for 4 years. On admission he had extensive cutaneous xanthomatosis. There was glycosuria and ketonuria. The blood sugar 5½ hours after the morning dose of insulin was 0.198%, and there was intense lipaemia. The plasma fat was 9.59% and the cholesterol 1.44% (Table III).

<sup>1</sup> A clinical account of this case has already been published [Bolam and Herbert, 1934].

On the day after these figures were obtained, the patient was put on a special diet containing 102 g. carbohydrate, 66 g. protein and 112 g. fat. Of the fat, 87.5 g. were given as butter, 16.5 g. were derived from eggs, 6.2 g. from milk and the remainder from vegetable sources. The fatty acids separated from a sample of the butter had i.v. 38.7 and the mean i.v. of the fatty acids of the food was calculated as 43. This diet was maintained throughout the whole period of study.

Under treatment the hyperglycaemia was controlled, the ketosis disappeared, the lipaemia diminished, and the cutaneous deposits of cholesterol were completely re-absorbed. The patient remained well, under treatment, for some months, but later died of scarlet fever.

#### DISCUSSION OF RESULTS.

It has been pointed out by Bloor [1921] that in diabetic lipaemia the increase in fats and lipoids occurs almost entirely in the plasma. This is illustrated in the present work by the data for the distribution of cholesterol between plasma and corpuscles (Tables I and III).

The fat in the plasma exists in an extremely fine emulsion, and shows no tendency to separate out on standing. Microscopic examination shows that the particles of fat are comparable in size with bacteria.

The high figures for fat and cholesterol here recorded—up to 22 % for fat, and up to 1.41 % for cholesterol in the plasma—are very unusual, but even higher figures have occasionally been reported. Among the highest in the literature are the following: for total fat, 23.7 % of whole blood [Fischer, 1903], 19.7 % of whole blood [Neisser and Derlin, 1904], 27 % [Frugoni and Marchetti, 1908]; and for cholesterol, 1.5 % of serum [Imrie, 1915], 2.14 % [Ringer, 1917], 2.6 % and 3.6 % [Adler, 1909].

At the height of the lipaemia, the most striking feature is the enormous increase in total fat, with relatively less increase in cholesterol and phospholipin, and the abnormally high proportion of fatty acids. The figures suggest the presence of a large amount of triglyceride, and this is confirmed by a consideration of the percentage composition of the fat in the only instance where the analysis is sufficiently complete to permit of such a calculation—namely, case R. W. July 30th (Table II). It is convenient to take the molecular weight of the fatty acids as 276, the figure obtained for the blood of the same patient on an earlier occasion, but the calculation is not materially affected by the choice of this figure rather than the molecular weight of any of the higher fatty acids ordinarily occurring in the body.

Of 100 g. total ether-soluble material, the following constituents were determined: phospholipin 6.33 g., free cholesterol, 5.64 g., cholesteryl ester, 10.76 g. (corresponding to 6.45 g. cholesterol in combination with fatty acid of mean molecular weight 276) and non-sterol unsaponifiable matter, 7.70 g. The sum of these constituents is 30.4 g. The "residual fat", which may be glyceride, amounts to 69.6 g.

As regards the fatty acids, the amount present in 100 g. fat is 75.7 g., and of this 4.42 g. are accounted for by lecithin and 4.65 g. by cholesteryl ester. The remainder of the fatty acids, which may be in combination with glycerol, amounts to 66.6 g.

This shows that 69.6 g. "residual fat" yield 66.6 g. fatty acid; that is to say, the residual fat is a substance yielding 95.7 % of its weight of fatty acid. This corresponds closely to the figure expected on the assumption that the residual fat is triglyceride, the theoretical value for which would be 96.7 %.

At the height of the lipaemia therefore the greatest increase is in the neutral fat. As a result of treatment, the total fat and cholesterol fall, but the fall of cholesterol is relatively less rapid than that of total fat, so that the cholesterol

forms an increasing proportion of the total fat. At the same time the fatty acid forms a decreasing proportion of the total fat. The results show that neutral fat diminishes more rapidly than cholesterol. Similar results have been reported by Bloor [1921].

In the present analyses, the cholesterol constitutes only 56-79 % of the total unsaponifiable matter. It is possible that some of the non-sterol unsaponifiable matter may be an artefact, derived from corks used during saponification and distillation. No tap-grease was used at any stage. Saponification of the cholesterol esters was proved to be complete, for the whole of the cholesterol in the unsaponifiable matter could be precipitated by digitonin. It is of interest that the sum of fatty acids and unsaponifiable matter constituted from 85 to 95 % of the total fat. The amount lost during saponification was approximately what would be expected to disappear (glycerol, choline and phosphoric acid). However, it is possible that the real loss was rather greater but was partly balanced by the introduction of extraneous material. Imrie [1915] has described a case of diabetic lipaemia in which the fat amounted to 14.06 % of the serum, and the cholesterol to 1.5 %; he found that the cholesterol accounted for 98 % of the unsaponifiable matter.

As regards the i.v. of the fatty acids, it is impossible to generalise, and the three series of data must be considered separately.

In the first series of data on R. W. (Table I), the i.v. at the height of the lipaemia was 68.5. This figure was obtained about 4 hours after a meal containing fat, but since at that time the total fat in circulation must have been about 560 g., the fat derived from the recent meal must have been a very small proportion of the whole. No food had been taken on 21. iii. 34 and the fats taken on the next two days were the fats of a mixed diet. The i.v. 68.5 is distinctly higher than one would expect from a mixture of the food fats, and it seems probable that the fat came from the patient's own tissues, probably from fat depots in adipose tissue, or partly from those depots and partly from the more unsaturated tissue fats. The results during the period of the experimental diet, when recovery was well-advanced, show that the i.v. of the plasma fatty acids rose during recovery, although the patient had for some days taken a diet in which the more saturated fats predominated, and although the blood was taken during fat absorption. The balance experiments made at this time showed that at least 96 % of the fat in the food was absorbed.

When R. W. was admitted for the second time (Table II) the first blood sample was taken during recovery from coma under treatment with glucose and insulin. The i.v. of the separated fatty acids was 86.8. The total fat in circulation would then be about 270 g. The patient had not taken any gross amount of fat before admission, and the i.v. is higher than that of mixed food fats. The fat must have come from the patient's tissues, and as the i.v. is higher than that of storage fat, some at least was probably derived from the more unsaturated tissue fats.

The sample of 3. viii. 34 was obtained 5½ hours after the first meal taken after recovery from coma. The fat from the recent meal may have affected the figure somewhat, but in view of the total fat in circulation it could not have predominated. There must have been other relatively saturated fats beside those of the food. In the later samples as recovery advanced, the mean i.v. of the fatty acids in the plasma became definitely higher than the mean i.v. of the fatty acids in the food.

In the series of data for K. U. (Table III) the results are very regular. There was a relatively low i.v. at the height of the lipaemia (54.5) and the i.v. steadily

rose during recovery, although the mean I.V. of the fatty acids of the food was low.

Upon the whole, it seems that at the height of the lipaemia much of the fat is derived from the patient's own tissues. It is probable also that absorbed fat would remain in circulation longer than normally and contribute to some extent to the lipaemia. In the later stages of recovery the plasma contains a considerable amount of fatty acids more unsaturated than those of the food.

Other figures which have been obtained for the I.V. of the separated fatty acids in intense diabetic lipaemia are 73 [Imrie, 1915] and 60.6 [Fischer, 1903].

For normal human blood, there are few data for the degree of saturation of the fatty acids of plasma, and those that exist have been obtained by micro-methods of rather doubtful value. According to Boyd [1933] the I.V. of the fatty acids of plasma, in the fasting state, ranges from 64.5 to 102. For the fatty acids of whole blood, McClure and Huntsinger [1928] found a range from 27 to 81, and Page *et al.* [1930] a range from 98 to 132. Figures for animal blood are more reliable owing to the use of large-scale methods. It may be calculated from the data of Bloor [1923] that the I.V. of the fatty acids of the plasma of the pig is on the average 93.8, and of the plasma of the ox, 109. Most of the figures show that normal blood contains fatty acids of a mean I.V. intermediate between the fatty acids of adipose tissue and those of true tissue fats.

Himwich and Spiers [1931] have reported that in depancreatised dogs the development of diabetic lipaemia is associated with a fall in the I.V. of the total blood fat.

In any attempt to interpret changes in I.V. during the development or the subsidence of lipaemia, it must be remembered that any change in the proportions of neutral fat and phospholipin is likely to affect the I.V. Boyd [1933] has shown that in normal blood the more unsaturated fatty acids occur especially in the phospholipin fraction. At the height of diabetic lipaemia the proportion of neutral fat is high, and as the lipaemia subsides the neutral fat diminishes more rapidly than the phospholipin [Bloor, 1921]. An increase in the proportion of phospholipin would involve an increased proportion of unsaturated fatty acids. This may in part explain the results of Himwich and Spiers and some of the results of the present paper. On the other hand, the present work affords one example of the mobilisation of neutral fat of relatively high I.V. In the blood of R. W. taken on July 30th, the neutral fat constituted 69.6 % of the total, yet the mean I.V. of the fatty acids was 86.8.

The cause of the lipaemia is obscure. It would be natural to suppose that the fat accumulates in the blood because it cannot be adequately oxidised. If this is the whole explanation, it is difficult to understand why so many patients have ketosis without any appreciable lipaemia. The patient R. W. had three severe bouts of ketosis, and had marked lipaemia on two occasions, but no appreciable lipaemia on the third. It seems probable that some other disorder of fat metabolism may exist besides the failure in oxidation which leads to ketosis.

#### SUMMARY.

Observations have been made on the blood fats in two cases of intense diabetic lipaemia.

At the height of the lipaemia the neutral fat, cholesterol and phospholipin are all greatly increased, but the greatest increase is in the neutral fat.

As the lipaemia subsides under treatment, the neutral fat diminishes much more rapidly than the cholesterol.

A consideration of the i.v. of the separated fatty acids at the height of the lipaemia suggests that the fat is derived from the tissues.

Comparisons between the fats of the food and those of the plasma have been made during the subsidence of the lipaemia under treatment. The mean i.v. of the fatty acids of plasma is always higher than that of the fatty acids in the food, and on the whole the i.v. of the fatty acids of plasma tends to rise as the lipaemia subsides.

I wish to express my thanks to Prof. Beattie and to Dr Mason Bolam for giving me the opportunity to make these observations on patients under their care, and to Dr Elsie Wright for her helpful co-operation in the study of one of the cases.

## CCXXII. FAT METABOLISM IN FISHES.

### VII. THE DEPOT FATS OF CERTAIN FISH FED ON KNOWN DIETS.

By JOHN ARNOLD LOVERN.

*From the Torry Research Station, Aberdeen, of the Department of Scientific  
and Industrial Research.*

*(Received June 22nd, 1935.)*

In a recent paper [Lovern, 1935] the writer has shown that the food fats of most fish are of a similar type to the depot fats of the fish themselves, and that a simple deposition of ingested fat, largely unchanged in composition, would account for the observed compositions of most fish depot fats. Another interpretation (not necessarily exclusive of the first one) will however fit the observed facts equally well. It may be that the whole life of the sea (both animal and vegetable) elaborates the same type of fat, which is thus typically marine, and that fresh-water life also elaborates its own special type of fat. There is abundant evidence moreover that certain fishes and other aquatic animals can modify their food fat very considerably to obtain a depot fat of a highly specialised character. Examples of such are certain elasmobranch fish and the toothed whales. The fact that certain other elasmobranch fish (*e.g.* the skate and thresher shark) and other varieties of whales exhibit no serious difference of type between their depot fats and their food fats may be due only to their own requirements being of the general marine type and not to any inability to modify ingested fat if and when necessary.

It would obviously help in deciding between these two interpretations if information could be obtained as to the type of fat laid down by fish, (*a*) on a diet containing fat of a non-aquatic type only and (*b*) on a fat-free diet. In case (*b*), any fat laid down would presumably have been synthesised from carbohydrate.

With the kind assistance of Mr W. Birtwistle, Director of Fisheries for the Federated Malay States and Straits Settlements, an attempt has been made to investigate these problems. At Singapore a species of carp, *Otenopharyngodon idellus*, is reared in shallow ponds dug in clay, and is fed only on grass. Two varieties of grass are used, elephant grass *Pennisetum purpurascens* (*P. setosum*), and Guinea grass, *Panicum maximum*. The only work on grass fats of which the writer is aware is that of Chibnall and Smith [1932, 1, 2] and Pollard *et al.* [1931] on cocksfoot and perennial rye grasses. From this it was expected that the elephant and Guinea grass fats would not be of the aquatic type.

In addition to these grass-feeding carp, the ponds contain two other carp, *Hypophthalmichthys nobilis* and *H. molitrix*. These fish act as scavengers, eating the faeces of *C. idellus*. In addition they eat the mud from the bottom of the ponds. This mud consists of fine clay reinforced with the faeces of *C. idellus* and with the rotting remains of unconsumed grass. These scavenging fish thus receive a diet almost free from fat (*cf.* p. 1896), but with presumably appreciable carbohydrate formed by bacterial action on rotten grass and in the faeces.

In some of the ponds small quantities of peanut cake are suspended in wire baskets and this is eaten from time to time by *H. nobilis* and *H. molitrix*. None

has ever been found in the stomach of *C. idellus*. The samples of *H. nobilis* and *H. molitrix* examined however had been reared in ponds in which no peanut cake had been suspended.

#### EXPERIMENTAL.

The grass-eating fish *C. idellus*, in addition to depositing fat in the body muscles, has a considerable quantity of fatty tissue around the intestines. The mud-eating fish has no appreciable quantity of this mesenteric fat.

Samples were sent from Singapore to Aberdeen in various ways. One consignment of *C. idellus* was sent in cold storage, and the body fat and mesenteric fat extracted at Aberdeen (1). A further supply of *C. idellus* flesh was minced at Singapore, desiccated with anhydrous sodium sulphate and sent over in tins, being extracted at Aberdeen. The mesenteric fat from these fish was rendered by simple heating at Singapore, and sent over in a small bottle (2). Later on a further batch of flesh and rendered mesenteric fat was received from *C. idellus* raised in ponds in which peanut cake had never been placed (3). The intestines of the frozen fish were crammed with grass, and it seems fairly certain that in any case this fish consumes no peanut cake.

Supplies of *H. nobilis* and *H. molitrix* flesh were obtained (packed with anhydrous sodium sulphate) from ponds in which no peanut cake had been placed.

Quantities of elephant grass, Guinea grass and the bottom mud of the ponds were also sent over after air-drying and were ether-extracted at Aberdeen. The extracted mesenteric fat from the frozen fish, after storage under nitrogen at  $-28^{\circ}$  for a few months at Aberdeen, had become largely ether-insoluble. The ether-soluble portion contained dibasic acids and it was evident that considerable oxidative breakdown had occurred. The writer has never previously encountered such a case, and presumably during transit from Singapore considerable quantities of peroxide must have been accumulated in the fat. This peroxide must then have decomposed when the extracted fat was stored under nitrogen at Aberdeen. The composition of the remaining ether-soluble portion of the fat is not included below, but it indicated that this mesenteric fat (1) was closely similar in composition to the body fat from the same fish (1). Mesenteric fats (2) and (3) were mixed to give an adequate sample for a full-scale analysis.

In several instances only sufficient fat was available for analysis by semi-micro-methods, and in these cases the results are only expressed to the nearest unit.

The particulars of the fish fats are given in Table I and the fatty acid compositions, as weight percentages, in Table II.

The two grasses proved to contain very little fat. The elephant grass (air-dried, as received) yielded 1.2 % of ether-soluble matter and the Guinea grass 0.95 %. In each case this was largely non-fatty in nature. In addition to chlorophyll the elephant grass extract contained 40 % of unsaponifiable matter and the Guinea grass extract 61.5 %. The saponifiable matter was a mixture of glycerides, phosphatides and waxes, which were not separated, as the combined acids were required even for analyses by semi-micro-methods. In any case, it

was knowledge of the total dietary fatty acids that was needed. The compositions of the mixed fatty acids are given in Table III as weight percentages.

The C<sub>18</sub> acids were presumably derived from the wax fractions. Both saturated and unsaturated acids contained at least 26 carbon atoms but were undoubtedly mixtures which were not further dealt with. The dried mud contained 0.17 % of ether-soluble material. The major portion of this was insoluble in light petroleum and therefore could not be true fat. The petroleum-soluble material had i.v. 57.5, and contained 57 % of unsaponifiable matter. The acids recovered after saponification were again largely insoluble in light petroleum and the final yield of true fatty acids was 0.007 % of the weight of mud. These fatty acids were of relatively high melting point, had i.v. only 50.0 and gave no ether-insoluble bromides. They appeared to contain some of the wax acids, which would be expected in the faeces of *C. idellus*, and obviously contained no polyunsaturated C<sub>20</sub> acids.

#### DISCUSSION.

It had been anticipated that the grass fats would be of simpler composition than is actually the case, and that apart from wax acids the fatty acids would be almost entirely palmitic and C<sub>18</sub> unsaturated acids. The occurrence of palmitoleic acid (and myristoleic acid) in these grasses is interesting, as they have only been found so far as plants are concerned in algae and other aquatic plants [Lovern, unpublished observations].

It must be remembered however (as mentioned by Tsujimoto [1925]) that most of the detailed work on plant fats has been limited to seed and fruit fats, whereas the work on aquatic plants (and these grasses) has involved the leaves and stalks of the higher plants and the whole thallus of the algae.

In view of the occurrence of these "aquatic" acids in the grasses, it is not certain that *C. idellus* is able to synthesise these acids from carbohydrate sources.

This fish also contained  $C_{20}$  polyethylenic acids, but the grass fats may well have contained small quantities of such acids, which were inseparable (with the small quantities of material available) from the unsaturated wax acids. It should be noted however that the proportion of available fatty acids in the grass diet is very low. Leaving out of account the unsaponifiable matter and the wax acids (which would not be assimilated), the elephant grass contains only 0.34% and the Guinea grass 0.17% of available fatty acids on the dry material. *C. idellus* contained a considerable proportion of fat to total body weight (3.7% in muscles (wet weight) in addition to the mesenteric fat). Whilst a slow accumulation of ingested fatty acids (together with a readjustment of the relative proportions of these) could account for the observed compositions of the fish fats, the available evidence, in the writer's opinion, is rather in favour of a synthesis by the fish, from carbohydrate or other material, of fatty acids of the desired type.

This view is strengthened when the results from the mud-eating fish are considered. The mud itself furnished a diet to all intents and purposes fat-free, and even the 0.007% of fatty acids which it did contain was free from polyethylenic  $C_{20}$  acids, whilst the fish eating this mud contained appreciable amounts of these acids in their fat. The only other source of ingested fat would be the faeces of *C. idellus* consumed directly. The mud would contain an appreciable quantity of these however and if the faecal fat had been considerable in quantity and of the "aquatic" type it should have been detected in the mud fat. Further, if *C. idellus* excretes any appreciable proportion of "aquatic" fatty acids in the faeces, this would render it almost certain that the fish synthesised its own depot fats, in view of the almost fat-free nature of the grass diet.

#### SUMMARY.

The depot fats from three species of tropical carp have been analysed. The first species was raised on a diet consisting only of grass, whilst the other two species lived on mud in which the organic matter consisted of the faeces of the first species together with rotting grass leavings.

Two species of grass were used, and both contained only small quantities of fat. This fat was found to be of an unexpectedly complete type and contained acids formerly encountered only in aquatic plants. The mud furnished a fat-free diet.

Whilst the complex nature of the grass fats makes the interpretation of the results less certain, the evidence taken as a whole indicates that these fish are able to synthesise fat of the desired type from carbohydrate or other sources.

# CCXXIII. STUDIES ON THE DISTRIBUTION OF ENZYMES IN DORMANT AND GERMINATING WHEAT SEEDS.

## I. DIPEPTIDASE AND PROTEASE.

## II. LIPASE.

By LIONEL BRADLEY PETT.<sup>1</sup>

*From the Biochemical Institute, University of Stockholm.*

*(Received June 24th, 1935.)*

## I. DIPEPTIDASE AND PROTEASE.

THE enzymes of wheat, especially amylases, have been the subjects of studies for many years, but, since most of the work has been done on flour or ground whole seeds, very little knowledge of the distribution in the seed has been obtained. Such knowledge is of great interest especially in relation to germination, because our information on the *in vivo* functioning and interrelations of intracellular enzymes, in general, is extremely meagre. The enzymic micro-methods originated by Linderstrøm-Lang and Holter [1934] conveniently permit, for the first time, a study of the distribution and activity of enzymes in relation to structure.

The present paper reports the distribution of dipeptidase (tested on alanyl-glycine) and protease (tested on edestin) in five easily-dissected parts of the wheat seed, both dormant and germinating. These parts are (1) the hull, including epidermal, parenchymatous and aleurone cells; (2) the endosperm, which stores starch and protein; (3) the scutellum, a yellow sheath of cells between the embryo and the rest of the seed; and the embryo, cut in a rather arbitrary manner into (4) cotyledon and (5) radicles. The importance of the scutellum as a site of enzyme formation and activity at the time of germination is, for the first time, emphasised with proteolytic enzymes.

The chief work on enzymes in germinating wheat has been done in Russia [see especially Bach *et al.*, 1927]. An increase in the content of amylase, catalase, peroxylase and protease on germination has been found. It is unfortunate that such an extensive investigation should have been done without regard to optimum  $p_H$  and on dried, ground, extracted seeds. The great irregularities observed are probably related to the fact that drying has a varying effect on the enzymes. The physiological factors involved in the germination of grasses have been systematically reviewed by Lehmann and Aichele [1931]. It should also be noted that many years ago the scutellum was suggested as an important functional part of grass seeds. Experimental evidence, however, has been lacking, except in some old, partly discredited, investigations on carbohydrases.

<sup>1</sup> Overseas Scholar (Canada) of the Royal Commission for the Exhibition of 1851.

## EXPERIMENTAL.

*Preparation of the enzymes.* The wheat used was Manitoba hard red spring wheat kindly supplied by Saltsjöqvarn, Stockholm. The dormant seeds were dried *in vacuo* over  $H_2SO_4$  for 24 hours. In germinated seeds the enzymic activity was determined directly on fresh tissue, but simultaneous moisture determinations were made, drying in the above manner. All results have been expressed in activity per mg. dry weight. Dissected tissue was kept moist in small test-tubes, containing moist cotton in the caps. Weighing on the micro-balance was done in a small, covered container, and the weighed tissue was put into a test-tube containing about  $8\mu l.$  of 60 % glycerol.

Dissection was carried out under a tripod lens. The epicarp over the embryo was removed, and then insertion and gentle prying with a blunt scalpel under the embryo caused it to come out quite cleanly. The embryo was at once cut in two along an arbitrary line which may be considered as the boundary between the cotyledon and the part containing the three radicles. A whole piece after weighing was used for each test. The embryo of more than 36 hours' germination was too large to use in such a manner. Since the work of Linderström-Lang and Holter [1932] on barley rootlets had indicated a localisation of the peptidase activity, it was considered inadvisable to try cutting up either the cotyledon or the radicles; therefore, no determination was made when they became too large to use in the above manner. Pieces of hull were cut off and cleaned from attendant, whitish, starch cells. A lateral section was made and pieces of endosperm prepared. To obtain the scutellum it was found most convenient to cut the seed along the same axis as the groove, after removing the embryo. The yellowish layer was then easily seen in each half and was removed free of hull and endosperm.

*Enzymic activity* was determined exactly as described by Linderström-Lang and Holter, using a burette of the type in which the mercury directly touches the solution. The procedure involves the direct titration of amino-groups by acid, in the presence of acetone, using naphthyl red as an indicator; the principle was explained by Linderström-Lang [1928].

## RESULTS.

The effect of drying the germinated seeds before or after dissection was to increase the apparent enzymic activity, as shown in Table I. The activity determined on fresh tissue, but expressed on the basis of dry weight, was consistently

Table I. *Dipeptidase activity in different parts of germinated wheat seeds, determined on fresh and on dried material, showing maximum and minimum means obtained in different series, and thus errors resulting from drying.*

	$\mu l.$ N/20 HCl per mg.			
	Fresh tissue		Dried tissue	
	12 hours	24 hours	12 hours	24 hours
Hull	$5.4 \pm 0.7$	$5.4 \pm 0.2$	42.0 21.1	24.9 11.5
Endosperm	$3.2 \pm 1.0$	$3.6 \pm 0.3$	0.3 2.6	7.0 0.7

smaller. Furthermore, the variation on drying was great. While it is possible to get the proper results by this procedure, the variations between the means of different series were large. Owing to these results it was decided to work with

fresh tissue. It seems possible that the effect of drying is to liberate the enzymes from zymogens which are supposed to exist in the cell, and that this liberation is irregular owing to somewhat varying internal conditions.

*p<sub>H</sub>-activity curves.* In common with most dipeptidases the optimum *p<sub>H</sub>* of that in wheat was found to be about 7.5. About the same curve was obtained for each part of the wheat. The protease, similarly to many plant proteases, has an optimum about *p<sub>H</sub>* 5.0, which is also the approximate isoelectric point of the substrate used, edestin. Table II shows the values found.

Table II. *Showing the activity of wheat dipeptidase and protease in relation to p<sub>H</sub>.*

Activity is expressed as $\mu$ l. of N/20 HCl.													
<i>p<sub>H</sub></i>	3.0	3.5	4.0	4.5	5.0	5.5	6.0	6.5	7.0	7.5	8.0	8.5	9.0
Protease	1.8	4.2	9.4	11.9	12.9	6.5	2.0	0.5	0	0	0	0	0
Dipeptidase	0	0	0	0	0	1.5	4.0	9.5	24.0	26.0	24.0	16.0	5.0

*Time of extraction with glycerol.* Whilst the best time varies a little with different parts of the seed and especially between dried and fresh tissues a standard time of 2 hours was adopted after various experiments. Table III shows typical results.

Table III. *Activity of dipeptidase in whole dormant wheat embryo, after extracting in glycerol for different lengths of time.*

Activity in $\mu$ l. N/20 HCl per mg.					
Time of extraction (min.)	20	40	60	120	240
Activity	6.0	8.0	9.0	11.0	11.3

*Time of digestion with substrate.* The time of 2 hours, at 40°, as used by Linderstrøm-Lang, was adopted. The digestion-time is always somewhat arbitrary, depending partly on considerations of initial velocity or equilibrium, and partly on the amount of hydrolysis required to give sufficient accuracy in the determination. Table IV shows the type of results obtained with the two enzymes.

Table IV. *The relation between the amount of hydrolysis of alanylglycine and of edestin by wheat embryos and the digestion time.*

$\mu$ l. N/20 HCl per mg.						
Time in hours	0.5	1	2	3	4	7
Dipeptidase	4.0	7.0	9.8	11.1	11.2	11.8
Protease	2.9	5.0	8.0	11.0	11.0	11.6

*The relation between enzyme concentration and activity,* as shown for both enzymes by using finely-cut pieces of dry cotyledon and varying the weight from 0.04 to 1.00 mg. was found to be linear. This fact justifies the conditions prevailing in this work, in which slightly different weights of tissue were used in each tube, and the titrations were corrected to a certain dry weight of tissue (1 mg.) for comparison.

*Accuracy of the results.* When the working conditions for the enzymes had been established the study of the relative activity in different parts of the seed was begun. Experiments with the five parts for any time of germination were made simultaneously, each being done in 6 to 8 tubes, and the whole series was repeated. The resulting averages are shown in Table V, Figs. 1 and 2. The

probable errors of the means are given in the Table, because these are rather higher than expected. The errors involved depend not only on the method of determining activity, but more especially on variations from one seed to another.

It should be noted that in every case of determining the activity in hull and endosperm at least one-third of the tubes showed no enzymic activity at all.

Table V. *Enzymic activity in different parts of the wheat seed during germination.*

Activity is expressed as  $\mu\text{l. N/20 HCl}$  per 1 mg. dry weight; the probable errors of the means are given.

Part of seed	Condition of seed		Germinating				
	Dormant		12 hours	24 hours	36 hours	48 hours	96 hours

Fig. 1. Dipeptidase activity of different parts of wheat seeds during germination.

Fig. 2. Protease activity of different parts of wheat seeds during germination.

The determination of protease activity by titrating amino-groups can be seriously criticised. Proteolysis probably begins with disaggregation of the protein molecule, a process ultimately producing polypeptides, which are hydrolysed by polypeptidase, giving titratable amino-groups. It is often possible to demonstrate the disappearance of precipitable protein before any change in titration has occurred. In the present work, however, some correlation was found, using a semi-quantitative turbidimetric procedure, involving the use of 20% salicylsulphonic acid. Both procedures showed the same optimum  $pH$  and the same relative activities for different times of germination.

## DISCUSSION.

It can be observed from Table V and Figs. 1 and 2 (1) that the hull and endosperm contain a relatively small amount of enzyme and that the amount does not change in a regular and significant manner on germination; (2) that the amount of enzyme is greatly increased, after 12 hours of germination, in the scutellum and embryo, the increase being somewhat greater in the cotyledon than in the radicles; (3) that after 12 hours the enzyme content in the embryo decreases fairly rapidly, but that in the scutellum it continues to increase for a time, later (after 36 hours) clearly decreasing but still maintaining a fairly high level. Slight differences exist between the curves for dipeptidase and protease.

The sudden increase of enzymic activity in the first few hours of germination is a familiar phenomenon associated with the change of the embryo from a dormant to an active condition.

It is well known that in germination the starch and protein of the endosperm ultimately appear in the embryo, usually as sugars and amino-acids, there to be used for building the new materials required by the developing plant. It has generally been suggested that the starch and protein are hydrolysed in the endosperm and then transported to the embryo, and enzymes are commonly held to be responsible for these changes. While some theoretical discussions have taken place, *e.g.* as to whether the enzymes are in the hull and embryo and are secreted into the stored food, little real knowledge, so far as the wheat seed is concerned, has been obtained. It is usually considered that a high enzymic activity in a given tissue indicates a site of formation, either for secretion or for doing the enzymic work, or possibly both. These considerations have a bearing on the results of the present investigation.

Since both hull and endosperm sometimes showed no proteolytic activity, never showed much and showed no change on germination, it can be doubted if they are the active centres in the proteolytic changes of the wheat seed. Furthermore there was no indication that the scutellum secretes enzymes into the endosperm, since no increase occurred.

The decrease of activity in the embryo after 12 hours is rather surprising since requirements must be increasing, even admitting that the proteolytic enzymes may not be the most important. This decrease was roughly proportional to the increase in total weight of the embryo, but since the dry weight was nearly constant, it is perhaps only an accidental relationship.

It would seem that the really significant observation is the large and continued increase in activity of the enzymes of the scutellum. The importance of the scutellum has long been suggested by some old work on amylase [see Lehmann and Aichele, 1931] and can be inferred from the work on barley by Euler and Sjöman [1933], but its full place in relation to all parts of the seed is only now emphasised. It may be possible that the scutellum performs all the functions required by the changes known to occur in the seed at this time.

## II. LIPASE.

Extraordinarily little work has been done on wheat lipases. It is, of course, generally thought that considerations of fat and fat hydrolysis in cereals are of minor importance. This conception has probably arisen from the low content of fat and the weak esterase activity, in comparison with *Ricinus*, for example.

Such a criterion is, however, not justified. It is probable that the fat in wheat, small though it is, and the lipase, weak though it is, can play a part in developing acidity as well as bad odours in stored flours. The present study can be of interest in this connection since it indicates the distribution of lipolytic activity in various parts of the seed.

From a physiological viewpoint the present study is of interest in demonstrating the changes of lipolytic activity on germination, though the significance of these changes is not obvious.

Apparently the only real study of wheat lipases is that by Sullivan and Howe [1933], working with ground wheat.

#### EXPERIMENTAL.

The wheat used, and the preparations made have been described in the preceding section. The method used was described by Glick [1934], employing methyl butyrate as substrate, glycine as buffer and involving an acid titration with the micro-apparatus of Linderstrøm-Lang. The method had to be modified owing to the weakness of the enzyme and the consequent small differences in titration. The modification consisted only in the use of  $N/40$  HCl instead of  $N/20$  for titration and doubling the quantity of indicator used. Even then the procedure was not wholly satisfactory, giving much less reproducible results than were obtained in the proteolytic studies.

An added difficulty was the rather high change in the titration value of the enzyme preparation on digestion without substrate. The correction was usually as large as the hydrolysis of substrate. This change may or may not be due to lipolytic hydrolysis of natural esters, since any change in the acidity of the tissue gives the same result, and there are various possibilities. The greatest corrections were found with hull and scutellum. A further difficulty is involved

Fig. 3. Lipase activity in different parts of wheat seeds during germination.

in trying to determine a  $p_H$  curve. The Glick method was of no value at a  $p_H$  lower than 7.5, partly because the initial titration is so low. In the present study therefore no optimum could be determined, a  $p_H$  of 8.2 being arbitrarily chosen in order to have suitable titration values. This is almost certainly not the optimum.

In spite of these difficulties some results were obtained which could be reproduced with fairly reassuring accuracy. These are presented in Fig. 3.

## DISCUSSION.

(1) The very high esterase content of the scutellum, possibly associated with the high fat content of this part, is very striking, as is the sudden drop in activity on germination. (2) By far the greater part of the lipolytic activity of the embryo is in the cotyledon, and this increases on 12 hours' germination and then decreases sharply. (3) The endosperm contains a high amount of lipase, second only to, but much lower than, the scutellum, and this amount increases in the first 12 hours of germination, then gradually decreases. This is of interest in connection with the accidental use of sprouted wheat for flour-making. (4) The hull contains an appreciable amount of lipase, and no change occurs on germination.

## SUMMARY.

1. A study has been made of the distribution of dipeptidase and protease in five parts of the dormant and germinating wheat seed, namely hull, endosperm, scutellum, cotyledon and radicula. Some conditions for the activity of the enzymes, relative to  $p_H$ , extraction, digestion time *etc.* have been determined.

2. The hull and endosperm sometimes showed no enzyme, and in any case only a very small amount which did not change significantly on germination.

3. The enzymes in the scutellum and embryo greatly increased in the first 12 hours of germination, after which they decreased in the embryo but continued to increase, for a time, in the scutellum.

4. The importance of the scutellum is thus emphasised, and the results are discussed in relation to popular conceptions concerning germination.

5. A micro-study has been made of the distribution of lipase activity in different parts of dormant and germinating wheat seeds. The results indicate high activity in the scutellum, decreasing on germination, whilst some parts show an increase in the first 12 hours and then a decrease.

The author wishes to express his gratefulness to Prof. H. von Euler for providing facilities in the Institute and for his interest in the work.

## CCXXIV. THE METABOLISM OF GALACTOSE.

### II. THE SYNTHESIS OF LACTOSE BY SLICES OF ACTIVE MAMMARY GLAND *IN VITRO*.

By GORDON ALLISON GRANT<sup>1</sup>.

*From the Department of Biochemistry, Lister Institute, London.*

*(Received June 27th, 1935.)*

ONE of the most interesting natural transformations in carbohydrate metabolism is that occurring in the active mammary gland during the synthesis of the galactose-containing disaccharide, lactose. Rohmann [1919] was able to obtain some evidence of the synthesis of lactose by the action of an extract of the mammary gland upon added sucrose. This investigator, on what now seems inconclusive evidence, suggested a stereokinase system, present in the blood as well as the gland and capable of causing the interconversions: glucose  $\rightarrow$  fructose  $\rightarrow$  galactose. More recently, Michlin and Lewitow [1934], using the minced mammary gland of lactating cows, have obtained an enzymic synthesis from added glucose and galactose of a disaccharide, which is hydrolysed by emulsin and is presumably lactose. Bert [1884] and later Porchet [1909] claimed that in animals which had previously had the mammary gland removed and subsequently became pregnant, hyperglycaemia developed and the sugar appearing in the urine was not lactose but glucose. Widmark and Carlens [1925] reported hypoglycaemia in lactating cows during milking, the degree roughly corresponding to the amount of milk produced. Paton and Cathcart [1911] obtained evidence to indicate that the glucose of the blood is used in the mammary gland during the formation of lactose. Harding and Downs [1929] were unable to demonstrate a lowered blood sugar in freely lactating women while on a hospital diet. They expressed the view that the amount of glucose circulating in the blood is controlled by the internal secretions rather than conditioned entirely by the lactose output of the active mammary gland. Nitzescu [1925] has been able to show that in fasting there is a drop in the lactose concentration of the milk produced by animals in full lactation. Upon the intravenous injection of glucose, galactose, fructose or maltose, the normal level of the milk lactose is restored. Injection of sucrose or lactose was without effect—these sugars are not utilised since there is no effective concentration of sucrase or lactase in the blood—and the disaccharides administered are, for the most part, excreted into the urine, owing to the low renal threshold for these sugars. The results of Nitzescu are explicable equally well by the assumption of a direct synthesis of lactose from the sugars administered by the active mammary gland, or by the previous conversion of these sugars into glucose, by way of glycogen formation in the liver.

Thus the available physiological evidence suggests that the freely lactating gland is apparently capable of withdrawing glucose from the blood and converting it into the milk sugar, lactose. The gland is automatically supplied with a surplus of blood sugar to meet the demands of milk formation, the stimulus emanating from some other source than the mammary glands themselves.

<sup>1</sup> Beit Memorial Research Fellow.

It is considered that the development of the mammary glands occurs under the influence of oestrin and progestin, and that the hypophyseal prolactin then causes the actual secretion [cf. Turner and Gardner, 1931; Turner and Frank, 1932; Gardner and Turner, 1933; Riddle *et al.*, 1933; Allen *et al.*, 1935; Lyons *et al.*, 1933].

Nelson [1934] and Nelson and Smelser [1933] suggest that a sudden fall in the amount of the ovarian hormone may act as a stimulus to the hypophysis for prolactin secretion. Selye *et al.* [1934] claim that the act of suckling reflexly maintains an adequate prolactin secretion; if this is interrupted by hypophysectomy lactation ceases. Grauer and Robinson [1932] observed milk secretion in transplanted mammary tumours, which is evidence that the nervous mechanism is not essential to milk production.

In the present investigation lactose synthesis has been demonstrated and quantitatively investigated with tissue slices of the active mammary gland, maintained *in vitro* under conditions as nearly as possible physiological, using as substrates the hexoses, glucose, fructose, mannose and galactose. The mechanism seems to a large extent specific, for under conditions of almost complete conversion of glucose into lactose only a small amount of synthesis occurred from fructose, mannose or galactose.

#### EXPERIMENTAL.

Mammary glands of freely lactating guinea-pigs were removed at periods from 2 to 5 days after the birth of the young. The animals were kept with the young until the time of the experiment, since this ensures an active stimulus to milk formation, coupled with the minimum amount of residual milk in the gland. A single gland was used for each of the four series of experiments, in order to obtain as nearly as possible comparable results with the different sugars. The tissue slices (approximately 0.5 mm. thick) were washed once in a physiological salt solution (10 : 3 : 0 [Robison and Rosenheim, 1934]) kept at 37°, and saturated with a mixture of O<sub>2</sub>, 95 %; CO<sub>2</sub>, 5 %. After quickly removing the excess solution by means of filter-paper, the slices were transferred to 25 ml. flasks, in some of which were 2 ml. of the above basal solution, saturated with the O<sub>2</sub>-CO<sub>2</sub> mixture, whilst others contained in addition 0.4 % (approximately) of the particular sugar under investigation. The flasks, tightly stoppered, were kept in a thermostat at 37°, with constant shaking, for a period of 6 hours. The wet weight of the tissues was obtained by weighing the flasks before and after the addition of the tissue slices and again at the end of the experiment. The dry weight was calculated from the H<sub>2</sub>O determination (3 hours at 110°) carried out on aliquot slices of the gland in each of the four series. At the end of the experiment the supernatant fluid was transferred to a 20 ml. flask and the tissue slices were removed and ground with sand in a mortar and quantitatively transferred to the same flask; 1 ml. of 10 % ZnSO<sub>4</sub>·7H<sub>2</sub>O solution was added, followed by 1 ml. of 0.5 *N* NaOH, added slowly with shaking. The contents of the flask were diluted to 20 ml. and filtered. The sugar estimations were carried out on these protein-free filtrates; in the fructose and galactose experiments a 1 in 2 dilution of these filtrates was used.

#### *Estimation of the hexoses and lactose.*

The fractionation of the reducing substances of the deproteinised filtrates into "fermentable sugar" and galactose was carried out by the general method of Harding and Grant [1933]. In the present investigation the method has been extended to include the quantitative estimation of lactose. All sugar reductions

were carried out with the Harding and Downs [1933] modification of the Shaffer-Hartmann Cu reagent using the requisite factor for the sugar concerned.

1. *Fermentable sugar* (glucose, fructose or mannose). 0.25 g. (wet weight) of washed baker's yeast was added to 10 ml. of the mammary gland filtrate and incubated with stirring for 30 minutes at 37°. Sugar estimations were carried out on 1 ml. portions of the clear centrifugate. This treatment removes glucose, fructose and mannose. The amount is estimated by difference in reducing power.

2. *Galactose*. 0.25 g. (wet weight) of "galac" yeast was added to the residual centrifugate and incubated for 30 minutes at 37° as in 1. The "galac" yeast used was a strain of English mild ale top yeast which had been adapted to ferment galactose at 80–100 % the rate for glucose [Grant, 1935]. This treatment removes galactose, and the amount is determined by further decrease in reducing power. In the filtrates from the galactose experiments, 0.5 g. of the yeast was employed.

3. *Lactose*. It has been found possible to remove lactose from its dilute solutions, in a similar manner, by the use of *S. fragilis*, a lactose-fermenting yeast. The yeast was grown on a 4 % fructose-4 % lactose mixture in a yeast extract, phosphate medium. 0.5 g. (wet weight) of the washed *S. fragilis* was added to the residual centrifugate after removal of the galactose and incubated as before at 37° for 30 minutes. By this treatment 90–100 % of added lactose is removed in concentrations up to 30–40 mg. per 100 ml.

Table I. *The synthesis of lactose from different hexoses by slices of active mammary gland in vitro. (6 hours at 37°.)*

The different yeasts can be kept at 4°, in the form of their 25 % wet weight suspension for 3 to 4 weeks and still retain most of their removal activity, provided they are washed at intervals of a few days. Their removal power is tested before the yeasts are used.

The results obtained in the present investigation are summarised in Table I. The amount of hexose added is given in each case, and also that present at the end of the experimental period. The lactose present in the tissues at the beginning of the experiment and at the conclusion is shown, and can be compared with the amount of this sugar obtained when the tissue slices were kept immersed in the solutions of the different hexoses, glucose, fructose, mannose and galactose.

#### DISCUSSION.

The results obtained show clearly that the active mammary gland possesses the mechanism required for the rapid synthesis of the galactose-containing disaccharide, lactose, from added glucose. There was but little evidence of such synthesis from the other hexoses investigated, fructose, mannose and galactose. Mannose appears to be more readily utilised, for the above purpose, than either galactose or fructose, though the difference is slight. It may be that mannose, fructose, and galactose require first to be converted into glucose, perhaps by the path of glycogen formation, before they can act as substrates for the synthesis of lactose. Lactose disappears from the mammary gland slices during the time of the experiment, and added lactose also undergoes a slow metabolism. For this reason the amount of lactose found does not represent the total synthesis occurring. However, from the amount of the added hexose remaining at the end of the experimental period, it is possible to obtain some idea of the amount which has been metabolised in excess of that finally present as lactose. This is considerable in the case of glucose but much less with the other three sugars. The small amount of fructose utilised by the active gland preparations, either in metabolism or for the synthesis of lactose, is especially noteworthy.

Svanberg [1930] found that an enzymic preparation of the parenchyma of the udder of heavy-milking cows could produce lactic acid from glucose, galactose, a mixture of the two and from lactose. Barrenschæen and Alders [1932] confirmed these findings and claimed that the capacity to produce lactic acid from galactose and lactose was a new function of the active mammary gland. They also suggested that hexosephosphates might constitute the intermediate material for the glucose-galactose conversion in the gland. Börst [1932] believes that the mammary gland stores organic phosphates in the periods between active lactation. In mammary tissues, and in many others, he found a phosphatase which could eliminate P from adenylic acid. This investigator considers that adenylic acid is important in the synthesis of lactose. Brenner [1932] found that while "lactacidogen" breakdown is complete in 2 hours, it takes 6 hours for the increase of inorganic P to cease during the autolysis of mammary gland tissue. Folley [1935] suggests that the phosphatase of the active mammary gland is probably identical with that of the kidney. He showed that it is able to catalyse the synthesis of sodium glycerophosphate.

Unpublished experiments of the present author have shown that the phosphatase of the lactating gland of the rabbit and the guinea-pig hydrolyses at approximately equal rates the following naturally-occurring hexosephosphates, 1:6-diphosphofructofuranose, glucose-6-phosphate, fructose-6-phosphate, trehalosemonophosphate and the synthetic ester, galactose-6-phosphate. It has been difficult to demonstrate synthesis of organic phosphates from added glucose and inorganic phosphate either by a "brei" or by tissue slices of the secreting

gland. A slight synthesis was observed in one instance in the presence of added hexokinase from yeast.

It is not yet possible to decide whether the phosphorylation taking place is connected only with the glycolysis of the active tissue, or whether it is also necessary in the series of changes taking place in the conversion of the glucose into lactose. It is of course quite possible that a new enzyme is formed by the lactating tissue for the conversion of the glucose to galactose, prior to the synthesis of the lactose.

In the experiments with galactose, there was no evidence of the reverse change of galactose  $\rightarrow$  glucose. Nor was there any evidence of the formation of noticeable amounts of free galactose from the hexoses investigated; the small quantities of this sugar found in some cases appeared equally in the control experiments. From this preliminary investigation therefore no evidence has emerged of the synthesis of galactose in the free state, but only of this sugar combined through its first C atom to the 4th atom of a molecule of glucose forming lactose.

#### SUMMARY.

The extent of the synthesis of the galactose-containing disaccharide, lactose, by the active mammary gland, when tissue slices of the lactating gland are kept immersed in physiological salt solutions containing different hexoses, has been determined. Of the hexoses used as substrates, glucose is readily converted into lactose, whilst there is but little evidence of synthesis from fructose, mannose and galactose. The lactose was estimated by the use of *S. fragilis*. Evidence was obtained of the presence of a hexosephosphatase in the active gland. A slight synthesis of organic phosphates from added glucose and phosphate was obtained in one experiment, when hexokinase from yeast was present.

# CCXXV. STUDIES IN TISSUE METABOLISM.

## VII. THE ACTION OF TUMOUR EXTRACTS ON HEXOSEDIPHOSPHATE.

BY ERIC BOYLAND AND MARGARET ESTHER BOYLAND.

*From the Research Institute, The Cancer Hospital (Free), London, S.W. 3.*

*(Received June 27th, 1935.)*

WARBURG [1930], CASE [1929] and BARR *et al.* [1928] have found that the active glycolysis of tumour tissue is destroyed by freezing and thawing. In the foregoing paper of this series [Boyland and Boyland, 1935] it was shown that extracts of frozen malignant tissue rapidly destroy adenylypyrophosphate—the coenzyme necessary for lactic acid formation in muscle extracts. We have found that tumour extracts convert hexosediphosphate into lactic acid, if relatively large amounts of adenylypyrophosphate are added in order to compensate for the destruction of this substance.

Meyerhof and Lohmann [1934, 1] have described an enzyme which causes reversible conversion of hexosediphosphate into dihydroxyacetonephosphate which they have named zymohehexase. Muscle extract forms a very active preparation of this enzyme which is, according to Meyerhof and Lohmann [1934, 2], 100 times as active as that from a mouse carcinoma (strain not stated). We have estimated the zymohehexase activity in extracts of tumours and muscle of mice and rats. In all our experiments the amount of zymohehexase in tumours was found to be greater than that found in mouse carcinoma by Meyerhof and Lohmann.

### *Estimation of zymohehexase.*

Weighed amounts of muscle and tumour tissue removed from freshly killed mice, rats and rabbits were minced in a well-cooled mortar. The tissue was ground with 2 vols. of water until frozen. After thawing and centrifuging for 15 mins. at 3000 r.p.m. the supernatant fluid was removed and dialysed against running tap water for 2 hours in a cellophane bag. The volume of the dialysed extract was measured, and small portions were incubated with hexosediphosphate in citrate buffer in an atmosphere of  $N_2$  and afterwards precipitated with trichloroacetic acid. For the determinations at zero time the extract was acidified with trichloroacetic acid before mixing with the substrate and buffer solution. The determination of alkali-labile phosphate was carried out as follows. 2 ml. of the solution to be determined were measured into each of two 15 ml. flasks, to the first of which an equal volume of 2*N* NaOH was added. After 15 mins., 1.4 ml. of 10*N*  $H_2SO_4$  were added to each flask and 2 ml. of 2*N* NaOH to the second flask. Molybdate and reducing agent were then added in the usual way. The difference between the amounts of phosphate in the two flasks was equal to the alkali-labile phosphate present.

In order to compare the activities of different tissue extracts the same concentration was always used and in every case approximately equal amounts of hexosediphosphate. Determinations of free and labile phosphate were then made for different times of incubation; the values were plotted against time and the time at which half the equilibrium amount of labile phosphate was

formed was determined graphically. It was found that if oxygen were not excluded from the incubation tubes the triosephosphate was slowly oxidised and low values of labile phosphate were obtained for times greater than 15 mins. If oxygen were excluded the equilibrium value remained constant for an hour. The times required to reach the half equilibrium value are given in Table I; in

Table I. *Zymohexase activity of tissue extracts.*

Tissue	Time required for formation of 50% of maximum triosephosphate (secs.)	Relative activity
Muscle (rabbit)	9	100
(rat)	15	60
(mouse)	20	45
Sarcoma 37 (mouse)	180	5.0
Crocker 180 (mouse)	210	4.3
Mal (mouse)	210	4.3
J.R.S. (rat)	210	4.3
Brain (rat)	210	4.3

all cases the values are averages of 2-6 determinations. Some similar determinations made with rat's brain showed that the rate of triosephosphate formation was identical with that of J.R.S. Zymohexase from tumour tissue and from muscle yielded no alkali-labile phosphorus compound from hexosemonophosphate (kindly supplied by Prof. Robison).

The results show that the zymohexase content of the grafted tumours examined is relatively constant and that it is about one-tenth that of muscle of the same animal. It is interesting to find that the zymohexase activities of rat and mouse muscle are significantly less than that of rabbit muscle.

The diminished labile phosphate formation in air suggests that the "Pasteur reaction" may possibly be concerned with this stage of glycolysis. The dialysed extracts could not convert the hexosediphosphate into lactic acid, yet in the presence of oxygen some of the triosephosphate formed from hexosediphosphate disappeared. The nature of the oxidation of the triosephosphate has not been further investigated, but the results suggest that oxidation in tumour extracts can remove triosephosphate, the first product of the decomposition of hexosephosphate, and thus prevent its conversion into lactic acid.

#### *Occurrence of dihydroxyacetonephosphate in tissues.*

Dihydroxyacetonephosphate and glyceraldehydephosphate are the only compounds known which yield inorganic phosphate rapidly in cold *N* NaOH solutions. Of these compounds only dihydroxyacetonephosphate has been isolated from tissues. If cold trichloroacetic acid extracts of tumour or brain tissue from which some free phosphate has been precipitated with calcium acetate or barium carbonate are examined it is found that an increase in the inorganic phosphate content occurs on standing 10 mins. in *N* NaOH. Estimations of this alkali-labile phosphorus in three different batches of J.R.S. showed that 0.02, 0.03, 0.04 mg. of P as alkali-labile phosphate per g. was present. The average of these figures would correspond to 0.15 mg. of dihydroxyacetonephosphate per g. of tumour. Similar estimations on two separate ox brain extracts showed 0.12 and 0.15 mg. of dihydroxyacetonephosphate per g. Until

the compound is isolated however this labile phosphate cannot be definitely attributed to a triosephosphate.

That tumour extracts form dihydroxyacetonephosphate from hexosediphosphate was confirmed by the isolation of the triosephosphate after incubation of tumour extract with hexosediphosphate and sodium sulphite. Sodium sulphite combines with dihydroxyacetonephosphate and hence all the hexosediphosphate in solution is converted into triosephosphate. The hydrolysis of the triosephosphate in *N* HCl at 100° was followed and the hydrolysis constant  $k = 33.2 \times 10^{-3}$  agrees with that found for pure dihydroxyacetonephosphate by Kiesling [1934].

*Lactic acid formation from hexosediphosphate.*

Extracts of rat and mouse tumours were prepared in a similar way to that described for the preparation of zymo-hexase but with only 1 vol. of water in order to keep the extracts as concentrated as possible. The extract was dialysed at 0° for 1 hour. Measured volumes of the dialysed extract were mixed in Thunberg tubes with various reagents in  $\text{KHCO}_3$  buffer; samples were removed for estimation of the original lactic acid content. The tubes were then repeatedly evacuated and refilled with  $\text{N}_2\text{-CO}_2$  mixture and incubated at 38°. At the end of incubation the samples were all precipitated with trichloroacetic acid solution (final concentration about 3%) and the estimations of lactic acid carried out by the method of Lohmann [1928].

Precipitation with copper sulphate and lime before estimation of the lactic acid was avoided, for in acid solution methylglyoxal has no effect on the estimation but if the solution is made alkaline methylglyoxal is partially converted into lactic acid and dihydroxyacetonephosphate completely so. Thus if the solution is never allowed to become alkaline the long extraction of methylglyoxal recommended by Stewart *et al.* [1934] is unnecessary. Some results shown in Table II demonstrate that the small lactic acid formation from hexosediphosphate is greatly increased by addition of adenylypyrophosphate.

No extracts have been found that will produce lactic acid from glucose. Lactic acid formation from hexosephosphate by active extracts of different tumours is shown in Table III.

Table II. *Effect of varying the adenylypyrophosphate concentration on lactic acid formation from magnesium hexosediphosphate by extract of Crocker 180 sarcoma.*

Exp.	Concentration of adenylypyrophosphate*	mg. lactic acid formed by extract from 1 g. original tissue	
		In 30 mins.	In 60 mins.
A	0.10	0.80	0.86
	0.40	0.64	1.54
B	Nil	—	0.71
	0.07	0.84	0.75
	0.13	0.74	1.02
	0.26	—	2.95

\* Expressed as pyrophosphate-P in mg. per ml.

These results confirm the suggestion that tumour extracts do not readily show lactic acid formation because of the extreme rapidity with which they decompose adenylypyrophosphate. Not all extracts which were made under similar conditions formed lactic acid from hexosediphosphate, although all the extracts tested for zymo-hexase contained this enzyme.

Table III. *Lactic acid formation from magnesium hexosediphosphate by tumour extracts at 38°.*

		0.22	—	2.21

\* Expressed as pyrophosphate-P in mg. per ml.

Two extracts were made from J.R.S. but neither of these showed any activity at all. This can be explained by the extremely rapid destruction of adenylypyrophosphate by J.R.S. extracts [Boyland and Boyland, 1935]. With our best conditions the extract corresponding to 1 g. of mouse tumour forms 2-3 mg. of lactic acid per hour from hexosediphosphate. Tumour slices under optimum anaerobic conditions (with  $Q_m^{N_2}=25$ ) form 10 mg. lactic acid per g. per hour from glucose but they will not form lactic acid from hexosediphosphate. It has been pointed out [Boyland and Mawson, 1934] that the glycolysis of hexosephosphate could not occur with whole cells because the phosphoric ester could not pass into the cells. But mouse tumour extracts can convert hexosediphosphate into triosephosphate more rapidly than the original cells can convert glucose into lactic acid, and they can convert hexosephosphate into lactic acid at one-quarter to one-third the rate of normal glycolysis. Moreover the conversion of hexosediphosphate into lactic acid necessitates the presence of the coenzyme adenylypyrophosphate which is rapidly broken down by the tissue extracts.

It is improbable that in extraction of the enzyme from tumour with an equal volume of water more than one-half of the activity would be found in solution. This loss, combined with the destruction of coenzyme which occurs in the extracts, shows that in the living cell hexosediphosphate would be converted into lactic acid as rapidly as glucose is transformed. It is thus possible that hexosediphosphate is an intermediate in tumour glycolysis.

It has been shown [Boyland, 1932] that whole tumour tissue contains adenylypyrophosphate. It is conceivable that the nucleosidases which attack adenylypyrophosphate in extracts are segregated in the living cell. One possibility is that the nucleosidases are in the nucleus, where the nucleic acid metabolism may occur, whilst the adenylypyrophosphate is in the cytoplasm where lactic acid formation takes place. These results explain why freezing and thawing of tumour tissue destroys the glycolytic power, whilst freezing and thawing of muscle does not greatly decrease the lactic acid formation. The rapid breakdown

of hexosediphosphate by tumour extracts along the same paths as occur in muscle extracts gives support to the idea that the mechanisms of lactic acid formation in tumour and muscle are similar.

The effect of freezing and thawing on the glycolytic process is possibly allied to the viability of the tumour under these conditions. Cramer [1930] has found the S 37 tumour to be more resistant to freezing than the J.R.S. The Mal. sarcoma (used in this work) is also fairly resistant to freezing and like the S 37 has given extracts after freezing which will convert hexosephosphate into lactic acid. The less viable J.R.S. has failed to give any glycolytic extract.

#### SUMMARY.

1. Dialysed tumour extracts contain zymohexase which converts hexosediphosphate into dihydroxyacetonephosphate. The zymohexase activity of tumour is about one-tenth that of the muscle of the same animal.

2. In the presence of oxygen, dihydroxyacetonephosphate is oxidised by dialysed tissue extracts to some more stable phosphorus compound. It is possible that the Pasteur effect might involve oxidation of triosephosphate.

3. Dialysed extracts of mouse tumours convert hexosediphosphate into lactic acid if sufficient adenylypyrophosphate is added to compensate for the rapid decomposition of this latter substance which occurs in tumour extracts.

One of us (M. E. B.) has pleasure in thanking the House Committee of the Cancer Hospital for a scholarship held during the progress of this work.

# CCXXVI. A NOTE ON THE PHOSPHORUS CONTENT OF MARINE ALGAE.

BY PAUL HAAS AND BARBARA RUSSELL-WELLS.

*From the Botanical Department of University College, London.*

(Received June 29th, 1935.)

IN a previous communication [Haas and Russell-Wells, 1923], dealing with the occurrence of ethereal sulphates in marine algae, it was stated that in *Chondrus crispus* evidence for the presence of phosphoric acid in organic combination had been obtained. This was shown by the fact that while no ionised phosphate could be detected before hydrolysis, its presence could be readily established after.

The occurrence of small quantities of phosphorus in sea weeds has long been known, but the actual amounts quoted in the literature are based upon ash analyses of the unwashed and undialysed weed. Such analyses give no indication as to the form of combination in which the phosphorus occurs in the weed or whether any of it is in organic combination and whether any such organic compounds, if present, are water-soluble. The present note is intended to throw some light on these questions. The weeds selected were *Chondrus crispus*, *Polysiphonia fastigiata* and *Dilsea edulis*, the two former because we had previously examined them from other points of view and the latter because of its relatively high phosphorus content.

In each case determinations of the total phosphorus content of the untreated weed and also of the dialysed aqueous extracts of the three weeds were made. Portions of the same extracts were hydrolysed with sulphuric acid under pressure and the ionised phosphoric acid thereby released was estimated; it was found that the whole of the phosphorus could be accounted for in this way, thus showing that the entire phosphorus content of the aqueous extracts was combined in the form of an ester of phosphoric acid. Furthermore a number of extracts obtained from samples of weed collected at different times of the year were examined for seasonal variation.

## METHODS.

The extraction in the case of *Chondrus* was carried out according to the method previously described [Haas, 1921] whereby two extracts known respectively as C.E. and H.E. were obtained.

The extracts of *Polysiphonia* and *Dilsea* were prepared by heating the weeds with distilled water over a water-bath and dialysing the resulting solutions until free from chloride and phosphate. Previous to analysis the dialysed product was tested for ionised phosphate, in all cases with negative result.

Preliminary experiments having shown that the phosphorus content of the weeds was very small, it was decided to employ a macrochemical method of estimation, since a larger quantity of material could then be used for analysis, thereby reducing the experimental error; Pemberton's volumetric method of analysis was selected. Of the various modifications which have been suggested by different authors we have found Richards and Godden's [1924] for biological

material to be best adapted to our requirements. Etheridge's [1931] observation that Richards and Godden's [1924] instruction to boil out ammonia is unnecessary was confirmed by our experience and this operation was consequently omitted. The exact details of the method of analysis employed are given below. An amount of material corresponding to just under 2 g. dry weight was dried to constant weight in a steam-oven; it was then transferred to a litre round-bottomed flask and gently heated with 10 ml. of concentrated sulphuric acid and 10 ml. of concentrated nitric acid over a gauze until brown fumes were no longer evolved. If the liquid was not colourless at this stage more nitric acid was added and the heating continued. When quite colourless the contents of the flask were washed into a large beaker and made just alkaline with ammonia (sp. gr. 0.880), which in most cases brought about the formation of a gelatinous precipitate of silica; the solution was accordingly filtered, made just acid with concentrated nitric acid, treated with 40 ml. of 50 % ammonium nitrate and heated to 70–75°: the phosphate was then precipitated by the addition of 30 ml. of Mathews's [1925] molybdate solution to which 1.5 ml. of concentrated nitric acid had been added. After standing overnight the solution was filtered through asbestos on a Gooch crucible; the precipitate was then washed twice with 10 % nitric acid, four times with 2 % ammonium nitrate and twice with cold water; it was then washed together with the asbestos into the original beaker by means of cold water and dissolved in a known excess of carbonate-free  $N/2$  NaOH, the excess being titrated back with  $N/2$  sulphuric acid using 6 drops of phenolphthalein as indicator. The factor 1 ml.  $N/2$  NaOH  $\equiv$  0.000596 g. P was used for the calculation.

For the estimation of the inorganic phosphate set free by hydrolysis of the ethereal phosphate in the aqueous extract the requisite amount of material was heated with 75 ml. of 5 % sulphuric acid in an autoclave at 105° for 4 hours: the resulting brown solution was filtered and precipitated as above. The results obtained are summarised in Table I.

Table I.

The figures give the mean % P calculated on the dry weight of the material analysed.

	Total P by oxidation		P by hydrolysis
	Extract	Weed	Extract
<i>D. edulis</i>	0.12	0.41	0.11
<i>C. crispus</i>	C.E. 0.030	0.22	C.E. 0.038
	H.E. 0.056		H.E. 0.050
<i>P. fastigiata</i>	April 0.075	0.22	April 0.073
	May 0.036		
	Aug. 0.045		
	Sept. 0.055		
	Oct. 0.022		

The agreement between values obtained for total phosphorus by oxidation and total phosphorus by hydrolysis is well within the limits of experimental error and accordingly justifies the conclusion that the entire phosphorus content of the extracts is present as an ester of phosphoric acid. Furthermore the figures given for the total phosphorus content of *Polysiphonia* extracts from weed collected in different months indicate that there is a slight, though not pronounced, variation in the ethereal phosphate.

## SUMMARY.

1. The total phosphorus in three algae, *Chondrus crispus*, *Polysiphonia fastigiata*, and *Dilsea edulis*, has been determined.
2. The total phosphorus in aqueous extracts of the above has likewise been determined.
3. The phosphorus in the said extracts has been shown to occur in the form of esters of phosphoric acid and to vary slightly in amount with the month in which the weed was collected.

# CCXXVII. THE *COLI*-TRYPTOPHAN-INDOLE REACTION.

## I. ENZYME PREPARATIONS AND THEIR ACTION ON TRYPTOPHAN AND SOME INDOLE DERIVATIVES.

BY FRANK CHARLES HAPPOLD AND LESLIE HOYLE.

*From the Department of Pathology and Bacteriology,  
The University, Leeds.*

(Received July 1st, 1935.)

WOODS [1935, 1, 2], in two papers on indole formation by *B. coli*, adequately reviews the position up to the present. In his own experiments, using twice washed and presumably viable suspensions of the organism, he demonstrates the complete oxidation of tryptophan to indole and concludes that five atoms of oxygen are required for each molecule of tryptophan used. He presents a strong presumptive case for the complete and quantitative breakdown to  $\beta$ -indolepropionic acid under anaerobic conditions. In the second of his two papers he examines the action of his washed suspensions upon a number of possible intermediates and he is forced to reject both the hypothesis of Harden [1930] and that ascribed to Raistrick by Cole [1933]. We ourselves, using dead suspensions of *B. coli*, have been unconsciously covering so much of the same ground that it seems advisable to publish those of our findings which bear upon the investigations of Woods.

Our first object was to obtain if possible an enzyme preparation from the organisms which would convert tryptophan into indole and this we have achieved by methods one of which requires the use of toluene and chloroform, which according to Woods prevent the reaction; it seems unlikely that these substances can be classed as simple enzyme poisons.

With regard to the actual mechanism of the breakdown of tryptophan to indole by *B. coli*, we began with a belief that the breakdown would occur *via* the unsaturated  $\beta$ -indoleacrylic acid in a manner analogous to the breakdown of histidine to urocanic acid [Raistrick, 1917] passing *via* the keto-acid to indolecarboxylic acid and thence to indole. This would account for the production of indolepropionic acid under anaerobic conditions and of indole under aerobic conditions. Unfortunately neither  $\beta$ -indoleacrylic acid nor indolecarboxylic acid gives rise to the production of indole when aerated with the indole-producing enzyme. In this direction our results are at the moment entirely negative, but it is possible that with enzyme preparations available this problem may be brought nearer to solution.

Indole in our experiments was determined by the method of Happold and Hoyle [1934]. Since the error in these estimations was  $\pm 5\%$  we have felt content with the method. Woods uses a vacuum distillation method since steam-distillation may cause decarboxylation of indolecarboxylic acid; this method seems unnecessarily time-consuming to us, and in many bacteriological media, especially media containing bile salts, in which we have had to estimate indole, the method would be impracticable on account of excessive frothing.

During the course of the investigation we have used many strains of *B. coli* isolated from both faecal and urinary sources and have also used old stock

cultures. Most freshly isolated strains are slow indole formers; in peptone water for example practically no indole is produced in the first 15 hours, whereas with old laboratory strains indole production begins almost at once and reaches a maximum within 12 hours. The addition of sodium deoxycholate in concentrations of 1/1000 or 1/2000, whilst it does not affect the rate of indole production of old strains, accelerates considerably the indole production of freshly isolated organisms. Higher concentrations of deoxycholate inhibit growth of the organism and consequently indole production.

Our work on enzyme preparation has been done with old laboratory strains which were powerful indole formers.

*Preliminary attempts to obtain an enzyme preparation.*

Our first experiments were done with living washed suspensions of *B. coli*. Such suspensions, continuously aerated at room temperature under toluene, were found to produce indole from tryptophan. This result led us to a series of attempts to produce a killed preparation which would show a similar activity.

Destruction of the bacteria by irradiation with ultraviolet light resulted in complete inactivation, as also did lysis with 1:50 sodium deoxycholate.

Shaking the suspension with toluene was found to be an uncertain method of killing the bacteria and resulted in considerable loss of potency of the preparation, but successful results were obtained by shaking with chloroform, and chloroform-killed suspensions have been used in most of our work. These suspensions however were found to deteriorate on keeping, and for this reason attempts were made to produce a desiccated preparation. This was achieved by precipitating the bacterial suspension with alcohol, washing with alcohol and with alcohol-ether, and desiccating *in vacuo*.

An attempt was made to obtain a cell-free preparation by suspending the bacteria in phosphate solution ( $M/5$ ,  $p_H$  8.5) and allowing to autolyse for 5 days. The suspension was then shaken with chloroform and centrifuged. The supernatant fluid was quite inactive, the chloroform layer was inactive, but the layer of intact bacteria retained some potency, though its activity was much reduced.

The enzymes appear to be strictly intracellular as the supernatant fluid obtained by centrifuging *B. coli* cultures or suspensions, after removal of indole by extraction with light petroleum and shaking with chloroform, is quite inactive.

The two successful methods which we have elaborated are described below.

*Methods of preparation of the indole-producing enzymes.*

(1) *Type of medium employed.* The medium used for the cultivation of the organism has a pronounced effect upon the potency of enzyme preparations. The most powerful preparations were obtained when the organism was grown on 1:10,000 tryptophan solidified with agar, with no other source of nitrogen and carbon ( $p_H$  7.8). This type of medium is however unsatisfactory for general use since, owing to the poor growth obtainable on it, the bulk of enzyme from a given number of Roux bottles is small. The ratio of potency to protein content of enzyme is however higher with this medium than any other.

Excellent results are obtained when the bacteria are grown on Fränkel's synthetic medium [Stephenson, 1930] + 1:10,000 tryptophan, a very potent enzyme resulting.

Media containing pure tryptophan are somewhat expensive, and for most purposes satisfactory results can be obtained by the use of ordinary nutrient agar or Fairchild's peptone agar.

The following results were amongst those obtained when chloroform-killed bacterial suspensions of approximately equivalent cell content were allowed to act on 2 mg. of tryptophan at room temperature at  $p_H$  8.5 for 40 hours. The number of Roux bottles required is given in brackets.

(1) 7.5 ml. of suspension from 1/10,000 tryptophan solidified with agar (18 Roux bottles). Indole formed: 0.65 mg.

(2) 7.5 ml. of suspension from Fränkel's medium *plus* 1/10,000 tryptophan (4 Roux bottles). Indole formed: 0.40 mg.

(3) 7.5 ml. of suspension from ordinary agar (3½ Roux bottles). Indole formed: 0.11 mg.

In the latest experiments, since it was desirable to obtain enzymes of greater potency, the bacteria have been grown on tryptic digest of caseinogen solidified with agar. A chloroform-killed suspension from 6 Roux bottles of culture producing 0.86 mg. of indole from 2 mg. of tryptophan is a typical finding. This represents almost 80% conversion. Such preparations are certainly much stronger in their ratio potency/protein content than those obtained on Fränkel's medium containing tryptophan 1/10,000; they are less powerful in this sense than those grown on tryptophan solidified with agar.

Experiments were done to determine if the presence of tryptophan in the medium is essential for the elaboration of the indole-producing mechanism. In one experiment a living suspension of *B. coli* from Fränkel's synthetic medium aerated under toluene with tryptophan for 36 hours completely failed to produce indole whilst a parallel suspension from ordinary agar did so.

In two later experiments, however, done with chloroform-killed suspensions from Fränkel's medium, some activity was obtained, in one case the potency being 1/10 and in the other 2/5 of the potency of parallel suspensions from Fränkel's medium + 1:10,000 tryptophan.

#### *Preparation of chloroform-killed bacterial suspensions.*

Bacteria are grown overnight on large Roux bottles of suitable medium. The bacteria are then washed off with saline, centrifuged, the supernatant liquid discarded and the deposit resuspended in saline, 10 ml. of saline being used for every 10 Roux bottles (average surface area 250 cm.<sup>2</sup>). The suspension is then extracted successively with light petroleum (B.P. 40–60°) until completely free from indole (about 4 or 5 extractions are usually necessary).

Chloroform is added to the indole-free suspension in the proportion of 1 vol. of chloroform to 2 vols. of suspension. The mixture is then shaken vigorously in a mechanical shaker (200 r.p.m.) for 4 hours. This has always been in our experience sufficient to sterilise. The emulsion is subcultured to verify its sterility, and used at once, no attempt being made to separate out the chloroform. Preparations made in this manner are very active, but should be used immediately since they show some deterioration on keeping.

The following is a typical result obtained with an enzyme preparation made in this way. (A similar method has been used by Gordon and Cooper [1932] in the preparation of bacterial phosphatase.)

#### *Action of chloroform-killed suspensions of B. coli on tryptophan.*

Flasks were set up as below, and continuously aerated at room temperature under toluene for 40 hours.

Flask (1): 7.5 ml. bacterial suspension, 4 ml. 1:2000 tryptophan solution 10 ml. phosphate buffer  $p_H$  8.4.

Flask (2): 7.5 ml. bacterial suspension, 4 ml. water, 10 ml. phosphate buffer  $p_H$  8.4.

Flask (3): 7.5 ml. bacterial suspension (heated at  $100^\circ$  for 5 mins.), 4 ml. 1:2000 tryptophan, 10 ml. buffer  $p_H$  8.4.

*Note.* 7.5 ml. of suspension were equivalent to the growth of 8 Roux bottles.

*Result.* Subculture of bacterial suspension: no growth.

Subculture of flasks (1), (2), (3) after aeration: no growth.

Indole content after 40 hours' aeration: (1) 0.20 mg. (2) Nil. (3) Nil.

A note is necessary regarding the accurate estimation of indole in this type of experiment. In estimating by the extraction technique, owing to the large amount of protein material present separation of the liquids may be incomplete, with the result that the final rosindole solutions contain precipitated protein. This precipitated protein should be removed, either by centrifuging or by diluting with 4 vols. of alcohol and filtering, before attempting the colorimetric estimation.

#### *Preparation of dried enzyme.*

Bacteria are grown on Roux bottles as above, washed off, centrifuged and resuspended in saline. The suspension is then treated with 66% alcohol (at  $0^\circ$ ), filtered through a Büchner filter and the precipitated bacteria are washed with ice-cold absolute alcohol and with ice-cold anhydrous alcohol-ether (1:2) and desiccated *in vacuo*. The dry preparation thus obtained is indole-free and usually sterile and has the advantage that it can be stored without apparent loss of activity. The following experiment illustrates its action on tryptophan.

#### *Action of desiccated B. coli on tryptophan.*

Flasks were set up as below and continuously aerated under toluene for 42 hours.

Flask (1): dried bacteria from 7 Roux bottles (0.224 g.), 4 ml. of 1:2000 tryptophan. 20 ml. phosphate buffer  $p_H$  8.4.

Flask (2): dried bacteria from 7 Roux bottles (0.224 g.), 4 ml. water. 20 ml. phosphate buffer  $p_H$  8.4.

*Result.* Subcultures before and after aeration: no growth.

Indole content: flask (1) 0.110 mg. (2) Nil.

#### *Factors modifying the action of the enzyme preparations.*

(1) *Aeration.* Indole formation by living cultures of *B. coli* is considerably affected by the degree of aeration, inadequate aeration resulting in a considerable reduction of the indole formed, and this was found to apply also to the action of killed suspensions.

The following results were obtained when 3.5 ml. of chloroform-killed suspension were allowed to act for 40 hours on 2 mg. of tryptophan at room temperature under toluene, one flask being continuously aerated while a parallel control was placed in a narrow tube plugged with cotton wool and not aerated.

Aerated flask: indole content 0.325 mg.

Unaerated flask: indole content 0.031 mg.

(2) *Reaction.* A number of experiments have been done to determine the effect of  $p_H$  on the activity of the enzyme preparation, the preparations being allowed to act on tryptophan in buffered solutions ( $p_H$  2-5 citrate, 5-8.4 phosphate, 8.4-11 borate). The optimum reaction was found to be  $p_H$  8.5. The activity dropped rapidly between  $p_H$  7.5 and 6.5, was almost negligible below

6.0 and finally terminated at 5.0. The alkaline limit was more variable, almost all preparations were active up to  $p_H$  9.5, the majority were inactive above  $p_H$  10.0, but occasional preparations were feebly active up to  $p_H$  11.0. It is probable that the alkaline limit of action is conditioned by the resistance of the cells to lysis by alkali, which resistance may vary with different preparations. The accompanying curve shows a typical result (Fig. 1).

Fig. 1. Effect of  $p_H$  on action of 3 ml. chloroform-killed *B. coli* suspension on 2 mg. of tryptophan; flasks aerated at room temperature under toluene for 40 hours.

(3) *Heat resistance.* All our preparations have been completely inactivated by heating to 100° for 5 mins.

(4) *Sodium deoxycholate.* It has been stated above that the addition of 1:1000 sodium deoxycholate to the medium accelerates the production of indole by certain freshly isolated strains of *B. coli*. This is not due to acceleration of action of the tryptophan-splitting enzymes, since the addition of this concentration of deoxycholate to enzyme preparations has a pronounced inhibiting effect on indole production. In one experiment parallel chloroform-killed suspensions were allowed to act on tryptophan in the presence and absence of 1:1000 sodium deoxycholate. In the absence of deoxycholate 0.4 mg. of indole was produced in 48 hours whilst in the presence of deoxycholate only a faint trace of indole was produced.

The effect of deoxycholate on indole production by the living organism must therefore be due to some other factor.

(5) *Effects of chloroform and toluene.* In a recent personal communication Woods suggested that some of the differences between his results and our own were due to differences in potency between his viable suspensions and our enzyme preparations and that chloroform and toluene exerted considerable inhibitory effects although they did not completely inactivate as was suggested in his paper. He pointed out that the yield of indole in his experiments was much higher than in ours. It must be noted however that whereas his experiments were done at 37° ours were done at room temperature. It was decided to extend our study under parallel conditions of the relative potencies of viable suspensions prepared by Woods's technique and enzyme preparations made by our methods, and also to study the effects of chloroform and toluene on these preparations.

(A) *Relative potency of viable suspensions and desiccated enzyme.* Bacteria were grown on Roux bottles of ordinary agar, washed off and divided into equal parts. One part was used to prepare viable suspensions by Woods's technique

and the other to prepare desiccated enzyme. Each preparation was then allowed to act upon 2 mg. tryptophan at room temperature for 48 hours and the indole produced estimated. The average results of 3 experiments were as follows:

Viable suspension from 6 Roux bottles yielded 0.26 mg. indole.

Desiccated enzyme from 6 Roux bottles yielded 0.21 mg. indole.

It appears that the desiccated enzyme is not appreciably less potent than the viable suspensions, the slight difference observed being probably attributable to slow growth of the viable suspensions.

(B) *Effect of chloroform.* Chloroform exerts a definite inhibitory effect upon the desiccated enzyme, the potency of preparations being decreased by 75–80 % when aerated in the presence of a layer of chloroform. Chloroform-killed suspensions show a reduced potency when compared with parallel viable suspensions, but it was not found possible to obtain an accurate comparison of the relative potencies since counts indicated that the viable suspensions were slowly growing and the reduction of potency is variable.

(C) *Effect of toluene.* It has been previously stated that shaking a bacterial suspension with toluene has much more inhibitory effect than shaking with chloroform. It was also found that the desiccated enzyme was very sensitive to toluene, a considerable reduction in its potency being obtained when aerated under a layer of toluene. In some of our original experiments we thought that the desiccated enzyme was inferior in potency to chloroform-killed suspensions and very variable results were obtained when desiccated preparations were used. It has later become evident that this apparent inferiority was really due to the great sensitivity of the desiccated preparation to toluene, and that the irregular results were due to variation in the degree of emulsification of the toluene layer which occurred during aeration. A somewhat unexpected result was obtained when the sensitivity of viable suspensions and chloroform-killed suspensions to toluene was tested. The activity of parallel suspensions with and without a layer of toluene was tested with the result that in both cases the indole production was more than doubled in the presence of toluene. It is suggested that this is due to removal of indole from the aqueous layer by the toluene, with a consequent acceleration of the reaction.

It is to be noted that when washed suspensions and chloroform-killed suspensions are aerated under toluene the toluene layer does not tend to become emulsified, whilst with desiccated preparations considerable emulsification of the toluene layer occurs and washed suspensions shaken with toluene tend to form stable emulsions. It is possible that the inhibitory effect observed with these latter preparations is largely physical.

*Action of the enzyme's on some possible intermediates of the tryptophan-indole reaction.*

Indole-3-aldehyde was prepared according to the original method of Ellinger [1906] and by the later and greatly improved method of Boyd and Robson [1935]. The details of the latter method were kindly supplied to us some time ago by Dr Robson to whom we would express our thanks. Both preparations were indole-free and had m.p. 194° (uncorrected). The enzyme preparation from 24 Roux bottles was made up to 40 ml. with saline and 20 ml. of the suspension were inactivated by boiling. Four aeration flasks were set up as follows and aeration continued for 2 days.

(1) 10 ml. enzyme + 10 ml. buffer  $p_H$  8.4 + 4 ml. 1/2000 tryptophan + 10 ml. toluene.

(2) 10 ml. inactivated enzyme + 10 ml. buffer  $p_H$  8.4 + 4 ml. 1/2000 tryptophan + 10 ml. toluene.

(3) 10 ml. enzyme + 20 ml. saturated solution of indole-3-aldehyde in buffer  $p_H$  8.4 + 10 ml. toluene.

(4) 10 ml. inactivated enzyme + 20 ml. saturated solution of indole-3-aldehyde in buffer  $p_H$  8.4 + 10 ml. toluene.

From the tryptophan present in flask (1) about 30 % of the theoretical yield of indole was obtained. No indole was detected in the others.

The concentration of indole-3-aldehyde has been varied considerably but in no single instance has indole been detected.

Growth experiments with indole-3-aldehyde also yielded negative results.

*Indolecarboxylic acid* was prepared both according to the method of Ciamician and Zotta [1888] from skatole and by that of Ellinger [1906] from the 3-aldehyde. The yields by both methods were extremely poor, the compounds appeared to be identical and had m.p. 214° (uncorrected). The four flasks set up with the aldehyde were duplicated with the carboxylic acid, 10 ml. of a saturated solution of the acid in phosphate buffer  $p_H$  8.4 were used. Indole was not detected.

*$\beta$ -Indoleacrylic acid* was prepared according to the method of Bauguess and Berg [1934]; the yield was again poor, m.p. 195° (uncorrected). The acid was tested with the enzyme preparation as above. The amount used was 10 ml. of a saturated solution of the acid in phosphate buffer. No indole production was detected.

Through the courtesy of Mr Woods who sent us specimens of indolepyruvic indolepropionic and indoleacetic acids we were enabled to examine the action of our enzyme upon these substances. No indole was produced from quantities of 2 mg.

#### DISCUSSION.

The name "tryptophanase" is suggested for the complete system of enzymes which induce and catalyse the production of indole from tryptophan and which are present in killed suspensions of *B. coli*. In our experiments we have restricted the concentration of tryptophan so as to obtain yields of indole which could be extracted and estimated without too much labour. An increase in the concentration of tryptophan in the system considerably increases the total amount of indole produced, though the percentage of tryptophan converted into indole is decreased. The greatest indole production has been obtained using a chloroform-killed suspension of *B. coli* which was grown on trypsinised caseinogen solidified with agar. The growth from 6 Roux bottles converted 80 % of 2 mg. tryptophan into indole when aerated at laboratory temperature under toluene. The same suspension converted 42 % of 5 mg. tryptophan into indole. It will have been noted that although *B. coli* grown on synthetic media free from tryptophan is not entirely deficient in tryptophanase the activity is considerably reduced, and that the most active preparations are those which have been grown on media with a high concentration of free tryptophan. It seems that the development of tryptophanase by the organism is controlled in part by the concentration of free tryptophan in the media. It is hoped to discuss this in a subsequent communication since we have reason to believe that we are dealing with an adaptive enzyme system.

With cultures grown on ordinary nutrient agar indole production has been greatest with washed viable suspensions of *B. coli* aerated with tryptophan under a layer of toluene. There is no doubt that under these conditions, whilst the suspensions may remain viable for a period greater than the duration of the

experiment, the death rate so exceeds the growth rate that viable counts at the end of the experiment are in the region of thousands per ml. as against thousands of millions in the absence of toluene. In many experiments the suspensions under toluene appear to be sterile. The maximum indole production from 2 mg. tryptophan using suspensions from 6 Roux bottles of ordinary agar under toluene was 0.58 mg. or a 50 % conversion. In the absence of toluene the yield was approximately 23 % of the theoretical. Indole is extracted from the aqueous phase by the toluene and it may be this removal of indole from the reacting system which accounts for the enhanced production under toluene.

It remains to explain the apparent inactivation of suspensions shaken with toluene at high speeds. Such suspensions form a very stable toluene-water emulsion and a coating of this emulsion probably interferes in a physical sense with the action of the enzymes. It has been noted that the dried preparation acting without toluene is approximately as effective as the chloroform-killed suspensions under toluene but that its activity is reduced in the presence of toluene. This has been discussed; the chloroform-killed suspensions remain separated in the aqueous phase whereas the dried product forms an apparent foam in a toluene-water emulsion. Woods obtained complete inactivation of his suspensions by shaking with chloroform and toluene, but it seems evident from our results that these substances cannot be regarded as enzyme poisons, although the potency of suspensions is reduced by shaking with chloroform and more markedly by shaking with toluene.

Working with viable suspensions, Woods showed that indole was not produced from indole-lactic, -propionic, -acrylic, -pyruvic, -acetic and -carboxylic acids, or from indole-3-aldehyde, and that whilst small amounts of indole were produced from the pyruvic acid in the presence of ammonia or other source of nitrogen this was probably due to synthesis of tryptophan which was then broken down. The preparations of tryptophanase which we have elaborated have similarly failed to produce indole from these derivatives (with the exception of indolelactic acid which has not been tested), so that in our present state of knowledge it is not possible to suggest a mechanism for the breakdown of the tryptophan side chain, and in particular the promising hypothesis of breakdown *via* the acrylic acid is not supported by experimental evidence.

#### SUMMARY.

1. Killed preparations of *B. coli* which convert tryptophan into indole have been obtained. The name tryptophanase is suggested for the enzyme system found in these preparations.

2. The tryptophanase is active between  $p_H$  5.0 and 10 with an optimum at  $p_H$  8.5.

3. The tryptophanase does not produce indole from indolepropionic indole-acetic, indoleacrylic, indolepyruvic or indolecarboxylic acid or from indole-3-aldehyde.

4. Tryptophanase is present in *B. coli* grown on synthetic media free from tryptophan, but the potency of preparations is much increased when the bacteria are grown on media with a high tryptophan content; the maximum potency is obtained when the bacteria are cultivated on a medium in which tryptophan forms the sole source of nitrogen.

The authors are indebted to the Medical Research Council for grants received and would take this opportunity of returning thanks.

# CCXXVIII. ENZYME SYSTEMS OF SARCOMA AND OF MUSCLE DEALING WITH HEXOSEPHOSPHATES.<sup>1</sup>

By FREDERICK HERMAN SCHARLES, MARY DWIGHT BAKER  
AND WILLIAM THOMAS SALTER.

*From the Collis P. Huntington Memorial Hospital of Harvard University, Boston.*

*(Received June 11th, 1935.)*

THE discovery of a peculiar carbohydrate metabolism in tumour tissue, first pointed out by Warburg *et al.* [1924; see also Warburg, 1931], has as yet led to no understanding of its cause. The chief obstacle to study of carbohydrate transformations in tumour lay in the failure of tumour extracts to produce lactic acid from glycogen or glucose. This impediment to progress has been commented upon by Boyland and Mawson [1934]. It has been found in this laboratory, however, that tumour extract will transform hexosephosphates into lactic acid [Scharles *et al.*, 1935]. In consequence it is now possible to compare in sarcoma and in muscle the enzyme systems which deal with hexosephosphates.

It has been observed [Scharles *et al.*, 1935] that in sarcoma extract the enzyme systems connected with hexosephosphate formation appear defective. Similarly, Matsuzaki [1933] has reported lack of "phosphatase" (*i.e.* phosphorylating enzyme) in minced tumour acting upon glycogen. It would be tempting to ascribe the peculiar carbohydrate metabolism of malignant tissue entirely to one such enzyme. First, however, one must be assured that all subsequent enzyme systems resemble those of a normal tissue like muscle. This paper reports observations which indicate that other enzymic differences actually exist, and that therefore the problem is complex.

In order to compare enzymic action in tumour extract with that in analogous extracts from normal tissue (like muscle), it is essential first to know the characteristic behaviours of both tissue enzyme systems. This paper reports optimum conditions for (1) the formation of phosphate esters from glycogen and inorganic phosphate, (2) the formation of hexosediphosphate from hexosemonophosphate, and (3) the breakdown of hexosephosphates into inorganic phosphate and lactic acid. Then, in order to separate the successive steps in this series of reactions, which normally merge smoothly one into another, use was made of toxic agents which check the progressive degradation at appropriate points. It has been shown, for example, that fluoride and iodoacetate inhibit formation of lactic acid from glycogen (or from hexosephosphate) at different stages in the breakdown of the substrate [Embden and Deuticke, 1934, 2]. This device has permitted the chemical dissection of the respective carbohydrate metabolisms of the normal and malignant tissues for purposes of comparison.

## *Discussion.*

In studying the peculiarities in tumour metabolism which lead to anaerobic glycolysis it is necessary to have for control a knowledge of similar processes in normal tissue. Of all normal tissues, skeletal muscle has been most intensively

<sup>1</sup> This work was aided by the International Cancer Research Foundation and the Ella Sachs Plotz Foundation.

studied along these lines. Muscle metabolism has therefore been used in these studies as a guide to the study of tumour.

As suggested in our previous communication, the behaviour of muscle extract can be described by the following schema: glycogen, after hydrolysis, is converted into (a) hexosemonophosphate, which, in turn, is converted by a second phosphorylating enzyme into (b) hexosediphosphate. By the action of appropriate enzymes the hexosediphosphate is split into trioses esterified with phosphate. These esters then undergo a series of chemical rearrangements in the three-carbon state [Embden and Deuticke, 1934, 1]. Ultimately lactic acid and free phosphate are produced.

This orderly series of reactions may be interrupted by "toxic" agents (like iodoacetate and fluoride) which interfere with enzymic activity. Iodoacetate appears to inhibit moderately the formation of monophosphate, and also moderately to check further esterification to diphosphate, as indicated in Tables I and III of this report. At any rate, it completely prevents lactic acid formation by muscle extract, as also described by Embden and Deuticke [1934, 2].

Likewise, in the presence of fluoride, even though glycogen is split and phosphate is esterified to a marked degree, the resulting ester, first described by Lohmann [1930] and identified as a mixture of phosphoglyceric and glycerophosphoric acids by Embden *et al.* [1933], is incapable of further change to lactic acid as long as fluoride is present (Table I).

Table I. *Effects of iodoacetate and fluoride on muscle and tumour extracts with glycogen. Incubated 2 hours at 40°.*

Extract	Poison	Final concentration of poison <i>M</i>	Lactic acid production millimols. per 100 ml.	Phosphate esterified millimols. per 100 ml.	Phosphate esterified %

The esterified product however when formed in the presence of fluoride and then isolated free from fluoride can be used by fresh muscle extract as a source of lactic acid. By contrast, in the presence of fluoride lactic acid may still be formed in appreciable quantity (Tables II and III) from both hexosemono- and hexosediphosphates prepared with yeast; but phosphate-esterification still proceeds more rapidly than its liberation from hexosemonophosphate.

As is well known [Scharles and Salter, 1934], tumour extract fails to produce lactic acid from glycogen although the splitting of glycogen is vigorous. The resulting carbohydrate complex (of unknown composition) cannot undergo further degradation to lactic acid. The data to be presented in this paper show that so little phosphate is esterified (Table I) by tumour at this stage, in contrast to muscle, as to suggest either (a) that different carbohydrate-phosphate

esters are formed by the respective tissue extracts, or (b) that tumour is deficient in phosphatase. Furthermore, what little ester is formed cannot be converted into lactic acid by tumour extract. Nevertheless, experiments now in progress show that the isolated phosphoglyceric acid and glycerophosphoric esters formed by muscle from glycogen in the presence of fluoride can be converted into lactic acid by tumour extract. This finding indicates that tumour contains an assortment of enzyme systems necessary for lactic acid production, as can also be demonstrated by artificially supplying hexosephosphates made by yeast (see Figs. 3-6). These hexosephosphates are also available sources of lactic acid when acted upon by muscle extract. Nevertheless, that distinct differences exist in the enzyme equipments of these respective tissue extracts may be demonstrated both by the course of hexose ester degradation and by the effects of toxic agents like iodoacetate and fluoride.

sometimes 37°, sometimes lower, *i.e.* 25°, because at higher temperatures the ester formed may be concurrently hydrolysed to a greater extent. (This latter condition is noticed most when lactic acid formation is not optimum because of insufficient coenzyme.)

The optimum  $p_H$  for muscle acting on glycogen was 6.8–7.2 for both lactic acid production and esterification (during 2 hours at 45°).

When tumour extract was incubated with glycogen no lactic acid was produced and there was only slight esterification of phosphate. Variations in temperature and in acidity had very little effect upon the amount of phosphate esterified. These results are illustrated in Figs. 1 and 2.

**Hexosediphosphate.** In Fig. 3, the optimum temperature for production of lactic acid and splitting of phosphate from hexosediphosphate by both muscle and tumour extracts is shown to be in the vicinity of 55°. The optimum  $p_H$  was very difficult to determine with hexosediphosphate substrate because the addition of phosphate buffer inhibited the reaction to some extent. The most favourable reaction seemed to be the  $p_H$  of the muscle extract itself, approximately 6.5. Therefore, in using hexosediphosphate as the substrate, it was neutralised to  $p_H$  6.8 before adding tissue extract.

Hexosediphosphate as substrate. o--o Muscle-lactic acid production. •--• Tumour-lactic acid production. Δ—Δ Muscle-phosphate hydrolysis. ▲—▲ Tumour-phosphate hydrolysis.

As illustrated by Fig. 4, the appearance of lactic acid was paralleled by the appearance of free phosphate in nearly equivalent quantity for the first 2 hours of incubation at 50°. Thereafter the rate of lactic acid production dropped off

whilst phosphate hydrolysis continued at the same rate for 2 hours further. This was true of both muscle and sarcoma extracts.

Fig. 4. Production of lactic acid and liberation of inorganic phosphate from hexosediphosphate by muscle and tumour extract, respectively. o-o Muscle-lactic acid production. •-• Tumour-lactic acid production. Δ-Δ Muscle-phosphate hydrolysis. ▲-▲ Tumour-phosphate hydrolysis.

**Hexosemonophosphate.** When fresh muscle extract was incubated at 50° with hexosemonophosphate solution for various periods of time there was a progressive increase in lactic acid. On the other hand, free phosphate decreased during the early period of incubation, to return eventually to its original con-

centration, and then progressively to increase. Similar experiments with tumour extract however failed to reveal any reversal of phosphate balance although

Fig. 6. Optimum temperature for production of lactic acid and esterification (or liberation) of inorganic phosphate by muscle and tumour extract, respectively. Fig. 7. Esterification of phosphate by muscle extract (but not by tumour extract) when incubated with hexosemonophosphate at varying temperatures.

lactic acid accumulated at approximately the same rate as with muscle. These results are shown in Fig. 5.

When muscle extract was incubated for 2 hours at various temperatures with hexosemonophosphate, lactic acid reached maximum concentration between 50° and 55°. With this long period of incubation however the amount of free phosphate showed the same reversal at lower temperatures as was encountered at 50° for a shorter incubation time. As shown in Fig. 6, maximum esterification of phosphate was found at room temperature, but maximum hydrolysis of phosphate was at 60°.

With tumour extract, the optimum temperature for lactic acid production was likewise 50° to 55°. At no temperature was any esterification observed. The optimum for hydrolysis of phosphate was similar to that of muscle.

Accordingly, the concentration of free phosphate may be regarded as a function both of time and of temperature. This relationship is given in diagrammatic form in Fig. 7. Comparison of the data for muscle with those for tumour discloses the absence of reversal in the latter case.

### III. *Effect of poisons.*

The effects of iodoacetate and fluoride upon the activity of muscle or tumour extracts were studied with glycogen, hexosediphosphate and hexosemonophosphate as substrates. These results are shown in Tables I, II and III respectively.

*Glycogen.* With glycogen, lactic acid production by muscle was almost completely inhibited by 0.0005 *M* iodoacetate or 0.005 *M* fluoride. Phosphate esterification was somewhat inhibited by iodoacetate, and greatly increased with fluoride. According to Meyerhof and Kiessling [1933] and Embden and Deuticke [1934, 1, 2] the esters formed under the influence of fluoride are the three-carbon esters, phosphoglyceric acid, and glycerophosphoric acid (see Table I).

When tumour extracts and glycogen were similarly treated, iodoacetate or fluoride in a concentration of 0.01 *M* showed almost no effect on the slight amount of esterification already present.

*Hexosediphosphate.* With hexosediphosphate stronger concentrations of poisons were necessary to affect the reaction. 0.05 *M* iodoacetate caused complete suppression of lactic acid formation with muscle extract, but only about 50 % inhibition with tumour extract. The effect on phosphate hydrolysis was about 50 % with muscle and hardly noticeable with tumour (see Table II).

A fluoride concentration of 0.05 *M* showed about 30 % inhibition of lactic acid production and phosphate hydrolysis with muscle and almost no effect upon tumour's action on hexosediphosphate.

*Hexosemonophosphate.* With the hexosemonophosphate mixture [Robison and Morgan 1930], iodoacetate in concentration of 0.01 *M* completely inhibited lactic acid production with muscle, and in concentration of 0.001 *M* markedly inhibited it. The effect on phosphate hydrolysis was slight. Again the action of iodoacetate on tumour activity with hexosemonophosphate was not marked; 0.05 *M* concentration reduced lactic acid production to 40 % but scarcely affected phosphate hydrolysis (see Table III).

Fluoride had almost no effect on the results with tumour extract acting on hexosemonophosphate. With muscle however 0.05 *M* fluoride caused some inhibition of lactic acid production and some accumulation of esters with hexosemonophosphate (as occurred also with glycogen).

### IV. *Effect of coenzyme.*

As is well known from the work of Meyerhof *et al.* [1931] and of Milroy *et al.* [1933] "rigor muscle" extract, in which the coenzyme adenosinetriphosphate has been broken down by the body enzymes before extraction, is incapable of

producing lactic acid from glycogen. The extract however can be reactivated by addition of small amounts of adenosinetriphosphate.

As reported by us previously [1935], tumour extract is also inactive with glycogen. It already contains small amounts of adenosinetriphosphate by analysis however and cannot be made to produce lactic acid by addition of more coenzyme.

"Rigor muscle" extract was still active towards hexosediphosphate, though to a less extent than fresh muscle extract. Tumour extract, which was dialysed 24 hours to remove the coenzyme, was still active with hexosediphosphate without any reinforcement.

"Rigor muscle" extract is also inactive with hexosemonophosphate and can be reactivated by addition of coenzyme. Dialysed tumour extract however was as capable of producing lactic acid from hexosemonophosphate as fresh tumour extract; and the addition of adenosinetriphosphate was without effect.

#### SUMMARY.

Enzymes which control carbohydrate metabolism have been examined as a possible cause for the peculiar carbohydrate metabolism of tumour tissue. To this end lactic acid production was studied, coincidently with phosphate esterification or hydrolysis of organic phosphates. When extracts of tumour and of skeletal muscle respectively were compared in their actions upon glycogen and hexosephosphate substrates, several differences were noted. These differences involved the effects of fluoride and iodoacetate, and of coenzyme deficiency.

Both tumour and muscle extracts produced lactic acid from hexosephosphates. Nevertheless tumour extract contrasted with muscle extract in the following features: (a) tumour extract remained unaffected by fluoride in its ability to produce lactic acid or to liberate phosphate from hexosephosphate esters; (b) tumour extract was much less susceptible to inhibition by iodoacetate; (c) tumour extract failed to esterify phosphate with hexosemonophosphate; (d) tumour extract produced lactic acid from hexosemonophosphate despite the depletion of coenzyme.

These findings suggest that, given an appropriate hexosephosphate ester from which both muscle and tumour extracts may produce lactic acid, nevertheless carbohydrate breakdown in the two tissue extracts proceeds along different paths.

# CCXXIX. THE METABOLISM OF LACTIC AND PYRUVIC ACIDS IN NORMAL AND TUMOUR TISSUES.

## II. RAT KIDNEY AND TRANSPLANTABLE TUMOURS.

By KENNETH ALLAN CALDWELL ELLIOTT,  
MARJORIE PICKARD BENOY AND ZELMA BAKER.

*From the Cancer Research Laboratories, Graduate School of Medicine,  
University of Pennsylvania, Philadelphia, Pa.*

(Received June 21st, 1935.)

In the first paper of this series [Elliott and Schroeder, 1934] a study was made by manometric and analytical methods of the oxidative breakdown of lactic and pyruvic acids in rabbit kidney cortex. It appeared that lactate is first oxidised to pyruvate and that the main course of the removal of pyruvate follows a cycle of reactions similar to that put forward by Toenniesen and Brinkman [1930] for muscle tissue. This cycle involves the oxidation of 2 mols. of pyruvic acid, probably by way of an unknown intermediary, to 1 mol. of succinic acid; succinate is then oxidised to fumarate, which, after conversion into malate, is oxidised to oxaloacetate, and oxaloacetate is decarboxylated yielding 1 mol. of pyruvate. The series of reactions is illustrated by the following scheme:

In this paper are presented the results of a corresponding study on transplantable rat cancers, and, for more direct comparison and further discussion, a set of results obtained with rat kidney cortex is given. The methods were similar to those described in the last paper with certain improvements. These results show that tumour tissue is completely unable to remove lactic and pyruvic acids by the above cycle of reactions, mechanisms for the catalysis of several of the steps being absent. In later papers we hope to follow the cycle in other tissues.

### Methods.

In general the methods used by Elliott and Schroeder were employed. These consisted in measuring the  $\text{O}_2$  uptake, respiratory quotient and acid change of thin slices of tissue in bicarbonate medium in an atmosphere of 95%  $\text{O}_2$  + 5%  $\text{CO}_2$  by means of the Dixon and Keilin apparatus [1933]; at the end of an experiment the contents of the manometer vessels were washed out quantitatively and

chemical estimations carried out on the fluid and tissue. Certain weaknesses in the estimations were discovered and modifications to overcome these are described below.

*Pyruvic acid estimation.* With the method of Clift and Cook [1932] inconsistent and low recoveries, 80–95 %, as judged by the titration of the acidity of pure pyruvic acid solutions using dilute NaOH and phenolphthalein, were obtained. The fault was found to lie in the fact that, after the addition of sodium bicarbonate suspension to break up the pyruvate-bisulphite compound, the bisulphite rapidly disappeared. If the mixture were allowed to stand for 10 min. at 22–24°, the amount of iodine required was reduced to 50–55 % of the theoretical. However, when the liquid was cooled to well below 10°, this loss was greatly reduced; recoveries of 96 % were then obtained consistently on immediate titration, and on standing 10 min. in the cold the recoveries only went down to 87–91 %. The method is therefore satisfactory provided that the solution is well cooled before adding the bicarbonate suspension and the titration is done immediately. It was found unnecessary to cool before adding the strong iodine to remove excess bisulphite; the loss due to dissociation of the bisulphite compound is slow, being about 5 % if there is a delay of 10 min. at 25° at this stage. The fact that the above source of error was not observed by Clift and Cook was probably due to the lower normal temperature in an English laboratory.

The necessity for cooling is removed if solid disodium hydrogen phosphate is used instead of bicarbonate suspension. After adjusting the initial point in the manner described by Clift and Cook, 2 g. of  $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$  are added and the iodine titration is carried out at once at room temperature. The titration goes more slowly, but cooling becomes unnecessary, recoveries are consistently good, 97–99 %, and there is no blank value as there is with bicarbonate. This modification has been adopted throughout this work.

Clift and Cook observed that glucose gives a small titration by their method, especially in the presence of amino-acids *etc.*, but that the effect of the sugar is avoided if the solutions are made acid before the bisulphite addition. Larger effects were found when glucose in bicarbonate-Ringer solution had been incubated and kept for some time in dilute acid as in a manometric experiment, and still larger effects when tissue had been present, even though the solutions analysed were about 0.03 *N* acid. Under constant conditions the titre is about proportional to the amount of glucose present, so that an illusory pyruvate disappearance is observed when glucose is being removed by glycolysis. The glucose effects are much reduced and this illusory effect disappears if 0.5 ml. of *N*  $\text{H}_2\text{SO}_4$  is added to the 5 ml. of solution before bisulphite treatment.

For example, in a normal experiment with tumour tissue in 3 ml. medium containing 7.2 mg. glucose initially, the fluid from the control (L) vessel, after making up to 25 ml. and analysing, apparently contained 0.28 mg. pyruvic acid and the fluid from the experimental (R) vessel, which had lost 2.1 mg. glucose by glycolysis, apparently contained 0.21 mg. pyruvic acid. In a similar experiment with 5 times the amount of glucose initially present the "pyruvate" found in the L and R vessels was respectively 1.40 and 1.24 mg. But when the extra acid was added before estimation in the above experiment with the normal amount of glucose the titres of both L and R vessel fluids were equivalent to only 0.11 mg. pyruvate, in another experiment to 0.06 mg., and in the experiment with five times the amount of glucose, the titres corresponded to 0.35 and 0.37 mg.

*Oxaloacetic acid estimation.* As Clift and Cook pointed out, the direct estimation of oxaloacetate gives uncertain results since increasing amounts of iodine are taken up owing to the formation of iodoform. Using the above alkaline phosphate method this effect seems even more pronounced, uncertain results as

high as 120–140 % of the theoretical being obtained. If however the solutions are made alkaline and heated on the water-bath for an hour as described by Clift and Cook for the removal of unstable carbonyl compounds, the oxaloacetate is completely changed into pyruvate, and satisfactory consistent titrations of 90–91 % are obtained. (Clift and Cook obtained 93 % for pyruvic acid itself after alkali-heat treatment.) Care must be taken to make the solution properly acid at the end of the alkali treatment by adding about 0.5 ml.  $N H_2SO_4$  more than is required to decolorise the thymolphthalein. All our estimations of oxaloacetate have been made by this method and the results corrected by multiplication by 1.10.

*Lactate and malate.* The method of Friedemann and Graesser [1933] was followed as before except that the acetaldehyde-bisulphite compound was split by the alkaline phosphate method. Instead of 15 ml. of saturated  $NaHCO_3$  solution about 2–3 g. of solid  $Na_2HPO_4 \cdot 12H_2O$  were added at the beginning of the titration and 1–2 g. more at the appearance of the end-point to ensure a sufficient amount. The recoveries were uniformly good, 97–99 %. A few more experiments were done on the extent to which malate and fumarate affect the estimation. The effect of fumarate is very small. Whereas 1 mg. of lactic acid corresponds to a titre of 11.1 ml. of 0.002  $N$  iodine, 1 mg. of fumaric acid requires about 0.3 ml. Malic acid has a considerable effect, 1 mg. requiring about 3.5 ml. of the 0.002  $N$  iodine. This method however is not suitable for the estimation of malic acid since the recovery varies considerably and also depends on the time (half an hour or overnight) during which the solution has stood with the  $Ca(OH)_2$ - $CuSO_4$  sugar-removing agent. Nevertheless, when conditions are constant the method is useful as a rough measure of the changes in malate concentration. It should be noted that for the purposes of this work 0.5 mol. malate corresponds to 1 mol. lactate or pyruvate. All the figures under  $Q_{LA}$  in Tables I to X were calculated as if the estimations were on pure lactate. With many of the figures in brackets the estimations were actually mostly of malate and in these cases an idea of the malate change is obtained by multiplication by about  $4.3 \left( \frac{11.1}{3.5} \times \frac{90}{67} \right)$ .

*Acetaldehyde.* In the previous paper it was mentioned that the presence of acetaldehyde in the manometer vessels could be detected by taking readings of the manometer at 37° and at 10°, since acetaldehyde condenses at 21°. More careful tests showed that, owing to the high solubility of acetaldehyde, vessel constants for this gas are very high, about 200, so that only large amounts would affect the manometer appreciably. In this work therefore we have estimated any acetaldehyde formed, in conjunction with the lactic acid estimation, by carrying out a preliminary distillation for about 10 min. without permanganate. To prevent any permanganate entering the distilling flask, the stem of the permanganate dropping funnel is filled with water. The distillate is collected as usual in a solution of bisulphite and subsequent estimation of bound bisulphite gives the amount of aldehyde. The bisulphite solution is then changed and the lactic acid determination carried out as usual. Tests showed that under ordinary experimental conditions, after the removal of glucose with  $Ca(OH)_2$  and  $CuSO_4$ , recoveries of 85 % of small amounts of added acetaldehyde were obtained. This was close enough as the method was used rather as a qualitative test. The traces of volatile carbonyl compound shown in the experimental part are entered as “acetaldehyde” and corrected for the low recovery by multiplication by 1.18. When the amount is appreciable, the pyruvic acid estimation has been corrected for the acetaldehyde which of course enters additively into that determination.

*Glycogen.* An appreciable and variable blank value of 0.03–0.045 mg. was found to occur in the method previously described. This was traced to a reducing impurity derived from the rubber stopper which holds the condenser tube into the centrifuge-tube during the HCl hydrolysis of the glycogen. By using a small glass funnel hanging in the centrifuge-tube, instead of the condenser, the blank values became lower and consistent at 0.02 mg.

*Solutions.* In the experiments with glucose this substance constituted 0.24 % of the medium. All the other substrates were added in the amount necessary to make the concentration in the medium 0.02 *N* (e.g. 4.02 mg. malic acid in the 3 ml.), except that with *DL*-lactate twice this concentration was used. The various substrates were made up in neutral solution in Krebs medium as previously described. For pyruvic acid it was found convenient to have a stock 5 % solution of the redistilled acid made up in Krebs medium, with water substituted for the bicarbonate solution. Immediately before use portions of this were neutralised with sodium bicarbonate-saturated Krebs medium and made up to the required volume with the medium.

The oxaloacetic acid used for this work was prepared from 50 g. ethyl sodio-oxaloacetate. The sodium was removed by shaking with cold dilute  $H_2SO_4$  followed by extraction with ether. After removing the ether, the ester was hydrolysed by treatment with 4 vols. of concentrated HCl for 48 hours [Simon, 1903]. Any crystals formed were collected, and a further yield was obtained by repeated extraction of the fluid with ether. After recrystallisation from acetone and benzene 3 g. of the acid were obtained, m.p. 147–148°.

*Manometric.* With two people working together at the manometric work, it was possible to run four manometers simultaneously with less delay between the death of the animal and the starting of the last manometer than in the previous work with only three manometers at a time. In the majority of the experiments in this paper the Keilin “danglers” were omitted, the substrate solution being pipetted directly into the vessel immediately before placing in the bath.

*Terms.* The terms defined in the first paper are used for this work and the methods for reducing analytical figures to those terms are shown in the protocol of that paper. However, in this and future work, we shall use the term  $Q_{13r}$  only in cases where it is probable that pyruvic acid itself is the main keto-body estimated. In other cases, such as with oxaloacetic acid, we shall use the term  $Q_{Keto}$  to include change in all carbonyl compounds (including any traces of acetaldehyde when this substance has not been estimated separately). The term  $Q_{Ald}$  will be used to describe changes in acetaldehyde.

Figures given in brackets under  $Q_{LA}$  refer to estimations which were given in whole or in part by malate although the calculation was made as though lactate alone were present. Where chiefly malate was being estimated, these figures, as mentioned above, should be multiplied by 4.3.

### Results.

*Rat kidney cortex.* For these experiments the kidneys of healthy large rats, weighing about 300 g., were used. Enough slices of cortical material could be obtained from the kidneys of one animal to put 60–90 mg. of moist tissue (10–15 mg. dry weight) in each vessel of four manometers. Roughly equal amounts of tissue from the two kidneys were put in each vessel. In Tables I and II results are given of experiments in the presence of glucose and in its absence. It is seen that the results are qualitatively the same in the two cases, and that the events are similar to those observed by Elliott and Schroeder with rabbit kidney.

† Done on tissue from a different animal.

Studying Table II we see that lactate has disappeared to the extent of 9.3 m.eq. (manometric equivalents) and this is reflected in the acid disappearance. The oxygen uptake is much increased and there is a rise in the R.Q. In the previous paper it was suggested that pyruvate was the first stage in the removal of lactate and that in the presence of excess lactate a little pyruvate (keto) appeared as a result of a dynamic equilibrium. The above experiment illustrated this clearly since lactate was added to the medium in the vessel immediately after introducing the tissue and not by means of dangles after the equilibration period. It was found that during the 18 min. elapsing before tipping acid into the left-hand vessel, pyruvate had accumulated at the rate of 3.5 m.eq. and had already reached more than half of the maximum amount found in the right-hand vessel after 108 min.

Succinate, fumarate and malate disappear, as acids, at about the same rate. Apparently the oxidation of succinate to fumarate by rat kidney proceeds considerably more rapidly than the further oxidation of the acids. This is indicated by the higher  $O_2$  uptake with succinate and the lowered R.Q. It has been mentioned that malate affects the lactic acid estimation considerably. This estimation thus brings out clearly the position of malate in the cycle. With succinate a considerable amount of malate appeared; with fumarate, which immediately precedes malate in the cycle, still more malate was formed, and with malate itself added, there was a large disappearance which would have been caused partly by oxidation and partly by conversion back into fumarate. The next two steps

in the cycle are oxaloacetate and pyruvate, both keto-bodies, and as would be expected, there is found to be some accumulation of such substances. (The R.Q. with fumarate and malate was raised considerably but did not reach the figure, 1.33, expected if they were being oxidised completely and no other oxidations were occurring.)

With oxaloacetate there is seen to be a very large disappearance of acid, part of which is due to decomposition to pyruvate, thus causing a very high R.Q., and part to the further oxidation of the pyruvic acid. It will be noticed that the keto-body disappearance is a little smaller but of the same order as when pyruvate is added directly, and the same applies to the lactate formed by reduction. As with rabbit kidney, acetate is oxidised to a certain extent as is indicated by increased  $O_2$  uptake, a raised R.Q. and some acid disappearance. The rate however is not sufficiently high to suggest that it is an intermediary in the breakdown of pyruvate, but there is the possibility that acetate may be oxidised *via* the cycle, being first converted into succinate.

For comparison with the above results, Table III gives a set of results obtained with rabbit kidneys using the improved pyruvate estimation. These

\* No danglers were used. Figures marked refer to pyruvate or malate formed during the preliminary 20 mins.

results agree completely with those given in the previous paper. In the experiment with fumarate, Keilin danglers were not used and during the preliminary 20 min. malate was formed in the left-hand vessel, before the acid was tipped in, at the rate of 9.1 m.eq. (as lactate) and, having reached equilibrium with fumarate, increased no further in the right-hand vessel during the experiment.

It is seen that lactate is less rapidly removed by the rabbit tissue than it is by the rat tissue. The same applies, and more strikingly, with added pyruvate. The rabbit tissue appears to remove pyruvate less rapidly than it does fumarate and the other substances of the cycle. Yet, if the cycle of reactions is to proceed, pyruvate should be oxidised at least as rapidly as fumarate; otherwise one would expect pyruvate to accumulate. It is possible that pyruvate added in a concentration of 0.02 *M* has an inhibitory effect on rabbit kidney. With rat kidney, the rate of pyruvate removal is very high, *e.g.* 26 m.eq. of keto-body. Some of this is reduced back to lactate, but the oxygen uptake, though much increased is not sufficient to account for complete oxidation of the acid ( $Q_A = 20.3$ ) disappearing. (1 m.eq. of pyruvate requires 2.5 m.eq. of  $O_2$  for complete oxidation.) It was pointed out in the last paper that the total oxygen uptake of rabbit kidney in the presence of succinate, fumarate *etc.* was not sufficient to account for complete oxidation of the acids disappearing. With the rat kidney the  $O_2$  uptake is sufficient but only if one supposes that oxidation of practically no other materials takes place (1 m.eq. of fumarate requires 1.5 m.eq. of  $O_2$ ). It is probable therefore that there is another course of metabolism of these substances which involves disappearance of carboxylic acid without complete oxidation. The estimations show that this is not a synthesis to glycogen. It may be

that other carbohydrates are produced, and this possibility will be examined in future work, although Ashford and Holmes [1931], who found a similar unaccountable disappearance of lactate with brain tissue, were not able to find a corresponding synthesis of carbohydrate.

It is necessary here to correct an error in the previous paper where the statements were made that kidney slices catalyse the decarboxylation of oxaloacetate and that the  $\beta$ -carboxylase responsible for the decarboxylation is destroyed by mincing the tissue. Proper controls now show that oxaloacetate, in bicarbonate medium at  $p_H$  7.4 and  $38^\circ$ , decomposes rapidly at about the same rate in the absence of tissue as in its presence. The misleading results with minced tissue are accounted for mainly by the greater dry weight of tissue used, which, divided into the  $CO_2$  evolved, gave a lower  $Q_{CO_2}$ . Low  $CO_2$  evolutions were also obtained probably because during the extremely hot weather when the experiments were made the neutralised oxaloacetate had decomposed considerably while standing. Further, the minced tissue seems to inhibit the autodecomposition of oxaloacetate slightly. Table IV shows the results of anaerobic experiments with

oxaloacetate and pyruvate. Oxaloacetate apparently gives a high  $Q_{CO_2}$  but the blank shows that  $CO_2$  is evolved at the same rate in the absence of tissue. In the two sets of experiments with rabbit tissue it is seen that spontaneous decomposition can account for the whole of the  $CO_2$  evolved by oxaloacetate, in spite of the fact that greater amounts of tissue were used than previously (which explains the lower  $Q_{CO_2}$ ). In each case with mince (0.35 and 0.30 ml. of tissue) the  $CO_2$  evolved was low, even though in one case the mince experiment was the first to be set up after neutralising the oxaloacetic acid. (The experiments are shown in Table IV in the order in which they were started.) In the presence of glucose, the negative  $Q_A$  is lower because the anaerobic glycolysis of the tissue compensates for the loss of acid groups from oxaloacetate. With rat kidney slices the table shows that, anaerobically, pyruvate suffers only a slight decomposition with production of a little  $CO_2$  and some reduction to lactate, the disappearance of

keto-body accounting for both. Estimating acetaldehyde as described in the first section, there was an apparent trace formed but this trace was also found in the absence of tissue. It seems certain that the decarboxylation of pyruvate is negligible and that no acetaldehyde accumulates. In calculating the  $Q$  values, the mean of the dry weights of tissue found in the left- and right-hand vessels was used, since kidney tissue in the right-hand vessel after an anaerobic experiment often weighs less than half of that in the left-hand vessel where disintegration has been checked by early acidification. The previous paper showed that  $\beta$ -hydroxybutyrate had practically no effect on the metabolism of rabbit kidney. With rat kidney we find that this acid is oxidised to some extent as is indicated by an increased oxygen uptake and some disappearance of acid. In Table V we

show these results together with a new experiment with rabbit kidney confirming the previous results. Another correction to the former paper is necessary here. Realising that small amounts of acetaldehyde formation would not appreciably affect the manometers but would affect the lactate determinations, acetaldehyde was estimated in the experiments with  $\beta$ -hydroxybutyrate according to the method described above. It was found that with rabbit and rat kidneys there was some acetaldehyde (or acetoacetic acid or acetone) formed but no lactate.

*Tumour tissue.* The experiments described below were done mostly with the Philadelphia No. 1 Rat Sarcoma described by Hueper [Waldschmidt-Leitz *et al.*, 1933]. A set of experiments with the Walker No. 256 Carcinoma is also shown. The tumours were taken 16-28 days after implantation and those used were either free of necrosis or had necrotic speckles fairly evenly distributed. As the slices were cut they were dropped serially into four small beakers containing the Krebs medium with  $O_2/CO_2$  bubbling through, so that using slices from one beaker for each manometer, the manometers each had a reasonably fair sample of tissue. To minimise the amount of lactic acid introduced into the vessels with the tissue, the tumour slices were kept in glucose-free Krebs medium until they were to be used. After rinsing in bicarbonate-free Ringer solution and weighing, they were put back into Ringer solution; the slices for both vessels of one manometer were then drained and introduced into the two vessels simultaneously so that the left- and right-hand vessels started as nearly as possible under the same conditions. The experiments showed that keeping the slices in the absence of glucose did not affect their subsequent behaviour with glucose. It may be mentioned that the ratio wet weight/dry weight of these tumours is high, being between 8 and 9.

Table VI shows the results of duplicate experiments with Phila. No. 1 tumour tissue. It is seen that good agreement in the  $Q_{O_2}$  and R.Q. is obtained. The figures for glycolysis do not agree quite so well. The lactate formation does not account completely for the acid formed; this has been found fairly consistently and indicates that aerobically some acid body other than lactate is also formed in small amount, and, as will be seen, this is probably succinate. To make sure that we were losing no lactate by incomplete extraction of the tissues, we have estimated the lactate in the last wash-water and in the undried tissue itself after grinding it up thoroughly with sand and deproteinising the extract. Not more than 0.04 mg.

lactate, corresponding to  $Q_{LA}=0.25$ , was found in either. In the anaerobic experiments, of which one example is shown in Table VIII, the lactate found was rather more than enough to account for the acid formation. The experimental period was in all cases 90 min. as with other tissues; the curve of the movement of the manometer fluid was quite linear in the absence of glucose, whilst in the presence of glucose, there was in all experiments a slight steady falling off in the rate of movement throughout the period.

In Tables VII to X are shown the effects of the various substances under consideration on the metabolism of tumour slices in the presence and absence of

Note. The metabolism was too small to give a reliable measure of the R.Q.

glucose. The experiments shown are representative and only when similar experiments have differed in some detail has more than one example of an experiment been entered. The effects of the presence of various substrates are more clearly seen in the experiments in the absence of glucose than in its presence since the high glycolysis in the latter case makes variations in  $Q_A$  and  $Q_{LA}$  more difficult to assess. Studying Tables VII and IX therefore we see that lactate is metabolised to a slight extent only and does not increase the oxygen uptake. With

succinate, fumarate and malate, we find a very striking difference between the behaviours of tumour and kidney tissue. The tables show that tumour is almost completely unable to metabolise these substances. There is no disappearance of acid, no increase in oxygen uptake and no significant change in the R.Q. The enzyme fumarase, which establishes an equilibrium between fumarate and malate, seems to be present however since, as judged by the "lactic acid" estimation, there is an increase in malate when fumarate is added, and a decrease when malate itself is added.

The case of pyruvic acid is interesting. Here there is a definite removal of pyruvate ( $Q_{\text{Keto}} = -9$ ). Part of this has been reduced back to lactate as with kidney, but the main amount has been otherwise dealt with, yet there is only a slight disappearance of acid groups. It seems clear that pyruvate has been oxidised to succinate and no further. The raised R.Q. is compatible with this conclusion since the oxidation of pyruvic acid to succinic acid has a  $\text{CO}_2/\text{O}_2$  quotient of 1.33. There is indeed not always an increase in the  $\text{O}_2$  uptake but this is readily explained by the sparing of other oxidations. There is no glycogen formation, and production of other carbohydrate is unlikely since so little acid has disappeared. This behaviour of pyruvic acid with tumour is of importance, since, whilst we have fairly direct evidence for the other steps in the cycle, this is the first clear indication which we have obtained of the transformation of pyruvate into succinate. Dickens and Šimer [1930] observed the effect of pyruvate in raising the R.Q. of tumour tissue and believed that this indicated oxidation of pyruvate in the normal manner. The fact that the acid disappearance does not correspond with the keto-removal shows that this is not so. The results with added oxaloacetate are what would be expected. The very high R.Q. and the acid disappearance are largely due to autodecomposition of oxaloacetate to pyruvate. But, as with added pyruvate, there is also a considerable removal of keto-body and a small reduction to lactate. The results shown in Tables VII and IX are very similar, showing that sarcoma and carcinoma have the same defects in their metabolism. In anaerobic experiments, tumour tissue shows no striking differences from kidney. As with kidney there is possibly a trace of decarboxylation of pyruvic acid but most of the keto-body disappearing is reduced to lactate. No acetaldehyde formation is detectable. Oxaloacetate decomposes to pyruvate at about the same rate in the absence of tumour tissue as in its presence. It may be mentioned that tumour slices do not disintegrate anaerobically as kidney slices do.

Study of Table VIII shows quite clearly that all the points discussed above hold true when glucose is present, if account is taken of the large lactic acid formation.

Meiklejohn *et al.* [1932] have shown that vitamin  $\text{B}_1$  is concerned in the oxidation of lactic acid by avian brain tissue. We therefore tried a set of experiments with tumour tissue with 0.5 mg. of a vitamin  $\text{B}_1$  concentrate<sup>1</sup> present in the 3 ml. of medium. No effect whatever was observed on respiration, glycolysis or metabolism of succinate or malate. Boyland [1933] showed that the respiration of Jensen rat sarcoma in the presence of lactate is not increased by vitamin  $\text{B}_1$ .

Included in Table VII are examples of experiments with formate,  $\beta$ -hydroxybutyrate and acetate. The previous paper showed that formate has no effect on the metabolism of rabbit kidney, and it is seen that the same is true for tumour tissue.  $\beta$ -Hydroxybutyrate scarcely affected the metabolism and acetate increased the  $\text{O}_2$  uptake only slightly without appreciable acid disappearance. It

<sup>1</sup> Obtained from Dr R. R. Williams of the Bell Telephone Laboratories.

is possible that acetate is normally oxidised first to succinate which is not further oxidised by tumour. This step might constitute a general point of confluence of fat and carbohydrate metabolism in cells.

In Table X are shown some experiments with minced tumour. They illustrate the well-known almost complete destruction of the respiratory and glycolytic mechanisms of tumour on mincing [Barr *et al.*, 1928]. It is also seen that the metabolism of pyruvate, which is shown above to appear in slices, is almost entirely stopped by mincing. In the previous paper it was shown that in minced kidney the succinic dehydrogenase remained very active. The fact that we find only a slight increase in respiration with succinate added to minced tumour is therefore further proof that tumour tissue is almost devoid of the mechanism for the oxidation of succinate.

#### DISCUSSION.

The results with rat kidney illustrate perhaps more clearly than those obtained with rabbit kidney [Elliott and Schroeder, 1934] that the main course of the metabolism of lactic acid in these normal tissues consists first in an oxidation to pyruvic acid, the pyruvate then being removed by a cyclic series of reactions whereby it is converted successively into succinate, fumarate, malate, oxaloacetate and pyruvate again in half the original amount. With rabbit kidney, it was necessary to assume that part of the succinate, fumarate and malate removed underwent some other change involving loss of acidity but not complete oxidation. The same applies to pyruvate with rat kidney, but with this tissue the oxygen uptake is sufficient to account for complete oxidation of the other compounds if we assume that practically no other substances are being oxidised at the same time. There is no obvious reason why this should not be possible. The dehydrases involved may be present in such high concentrations that, when saturated with their substrates, they are capable of excluding by competition the reduction of the cytochrome, yellow pigment and other intermediaries of tissue respiration, by other enzymes and their substrates. They would thus secure to their substrates nearly the whole of the oxygen made available by these mechanisms. Nevertheless it seems possible that, even with rat kidney, a part of the succinic, fumaric or malic acid removed undergoes an unknown change.

The majority of tissues which form lactic acid in the absence of oxygen show little accumulation of this substance in the presence of oxygen. It is believed that this is explained partly by an oxidative inhibition of the glycolytic mechanism [see *e.g.* Lipmann, 1933] and partly by oxidation of the lactate as it is formed [Krebs, 1931].

The high rate of accumulation of lactic acid in experiments with tumour tissue would be the resultant of the rates at which the acid is formed and removed. There is no doubt that in tumour lactate is formed at an unusually high rate anaerobically and that inhibition of the glycolytic mechanism by oxygen is not complete, but the work described above shows that the accumulation of lactic acid can be explained in part at least by a failure in the oxidation processes. The cycle of reactions we are considering is active in muscle [Needham, 1932] and in kidney, and future papers of this series will show whether it is significant in other tissues. Meanwhile, we see that two, and possibly three, of the oxidative mechanisms are not active in tumours. These are succinic and malic oxidases and possibly lactic oxidase since so little lactate is removed, even though the next step, pyruvate to succinate, seems to occur at a fair rate. The transformation of normal tissue to the malignant habit, then, seems to involve, among other things, the loss of function of these enzymes. It should be pointed out that the mechanisms lost on destroying the tissue structure of kidney by mincing [Elliott and

Schroeder, 1934], namely lactic, pyruvic and malic oxidases, are not the same as those missing from tumour tissue, since tumour slices appear to possess pyruvic oxidase and lack succinic oxidase. According to Barron [1932], slices of various strains of rat tumour, including the Walker No. 256, do possess a succinic dehydrogenase, judging by experiments on the anaerobic reduction of methylene blue. If this is so, it appears that the failure of tumours to oxidise succinate and perhaps also malate and lactate aerobically depends on the absence of some intermediary catalyst, such as cytochrome or the yellow pigment (flavo-protein) of Warburg and Christian [1932]. Cytochrome does not appear to be lacking in tumours [Yaoi *et al.*, 1928; Bierich and Rosenbohm, 1926], but György *et al.* [1934] have shown that the growth-promoting vitamin B<sub>2</sub>, which has been identified with flavin [György *et al.*, 1933], is present in very low concentration in tumours whilst it is high in liver and kidney. Euler and Adler [1934] have found the same distribution for flavins themselves. Nevertheless, flavo-protein appears not to catalyse the oxidation of succinate to fumarate [Wagner-Jauregg *et al.*, 1934, 1; Adler and Euler, 1935] and is therefore not necessary for this reaction. But Wagner-Jauregg *et al.* [1934, 2] showed that the yellow pigment is necessary for the anaerobic oxidation of malate and lactate with methylene blue. The lactic and malic dehydrogenases of heart muscle are apparently identical and both need activation by a coenzyme whilst the succinic dehydrogenase does not [Boyland and Boyland, 1934; Andersson, 1934]. Lack of enzyme, coenzyme or flavin might therefore explain the failure of tumours to oxidise lactate or malate. The failure in respect to succinate seems to require some other explanation.

Szent-Györgyi [1935; Gözsy and Szent-Györgyi, 1934] has recently stated that the reversible systems, succinate  $\rightleftharpoons$  fumarate, and malate  $\rightleftharpoons$  hydroxy-fumarate (oxaloacetate), occupy a central position as carrier catalysts for tissue respiration in general. We would agree in the importance of these reactions, but only as stages in the metabolic breakdown of carbohydrate *via* pyruvate, and perhaps in the metabolism of fat *via* acetate and succinate. Apart from the facts that Szent-Györgyi used abnormal material (minced tissue) for his work, and gave no proof of the actual reversion of the reactions during normal activity, we would point out that tumour represents a tissue which respire at a rate corresponding to that of liver, but in which a mechanism responsible for each of his postulated key reactions is missing.

#### SUMMARY.

1. Following the methods of Elliott and Schroeder [1934] with some improvements, a study has been made of the metabolism of lactic and pyruvic acids and of various other compounds by rat kidney cortex and by two types of tumours.

2. A method is described for avoiding a source of error in the Clift and Cook [1932] method for estimating pyruvic acid. Notes on the interference of glucose in this method are also given and the application of the method to oxaloacetate is described.

3. The previous paper showed that, in rabbit kidney, lactate is reversibly oxidised to pyruvate, which substance is removed mainly by a cycle of reactions involving the successive formation of succinate, fumarate, malate, oxaloacetate and finally pyruvate in half the original amount. This cycle is demonstrated more clearly with rat kidney. It is indicated that some pyruvic acid and possibly some of the other acids are removed by this tissue by a method which does not involve complete oxidation.

4. Oxaloacetic acid decomposes rapidly to pyruvic acid at 37° in neutral solution. Contrary to the statement in the previous paper, this reaction is not catalysed by kidney.

5. Acetate and  $\beta$ -hydroxybutyrate are oxidised to some extent by rat kidney. No lactate is formed from  $\beta$ -hydroxybutyrate; the apparent traces of lactate observed in the previous paper were due to acetoacetic acid, acetone or acetaldehyde affecting the lactate estimation.

6. With two types of tumour it is shown that the cycle of reactions mentioned above does not occur. Mechanisms responsible for two of the reactions are lacking, namely the oxidation of succinate to fumarate and the oxidation of malate to oxaloacetate. The oxidation of lactate to pyruvate also seems defective. On the other hand, the oxidation of pyruvate to succinate can proceed, and the establishment of an equilibrium between fumarate and malate does occur. These results are discussed in relation to the findings of other workers on enzymes and pigments in tumours.

7. Acetate and  $\beta$ -hydroxybutyrate are oxidised by tumours only to a slight extent.

# CCXXX. METABOLISM OF AMINO-ACIDS.

## IV. THE SYNTHESIS OF GLUTAMINE FROM GLUTAMIC ACID AND AMMONIA, AND THE ENZYMIC HYDROLYSIS OF GLUTAMINE IN ANIMAL TISSUES.

By HANS ADOLF KREBS.

*From the Biochemical Laboratory, Cambridge.*

(Received June 29th, 1935.)

### 1. Oxidation of *l*(+)-glutamic acid without formation of ammonia.

THE starting-point of this investigation was the observation that glutamic acid behaves differently from all the other  $\alpha$ -amino-acids in guinea-pig and rabbit kidneys, in that, although it increases the oxygen uptake even more than any other amino-acid of the *l*-series, in most cases it actually diminishes ammonia formation. In guinea-pig kidney, the oxygen uptake is increased about 100–150% (Table I) whilst in most experiments no ammonia at all is detectable in the presence of *l*(+)-glutamic acid [Krebs, 1933, 2]<sup>1</sup>.

Table I. *Oxygen uptake and ammonia formation in the presence of l(+)-glutamic acid.*

Tissue	Without substrate		With <i>l</i> (+)-glutamic acid ( <i>M</i> /50)	
	$Q_{O_2}$	$Q_{NH_3}$	$Q_{O_2}$	$Q_{NH_3}$
Kidney, guinea-pig	16.8	1.20	25.7	~0
	14.6	0.82	35.8	~0
	14.1	0.90	30.9	0.18
Kidney, rabbit	14.8	0.92	35.5	0.57
	13.8	0.37	23.4	0.40

However, if guinea-pig kidney is poisoned with arsenious oxide, ammonia is formed from glutamic acid (Table II). This could be explained by assuming that ammonia is formed in a primary reaction but disappears in a secondary reaction, the latter being inhibited by arsenious oxide. Experiments were therefore set up to see whether ammonia reacts in the expected way if it is added to kidney.

Table II. *Influence of  $As_2O_3$  on ammonia formation in guinea-pig kidney.*

Concentration of $As_2O_3$	Without substrate		With <i>l</i> (+)-glutamic acid ( <i>M</i> /50)	
	$Q_{O_2}$	$Q_{NH_3}$	$Q_{O_2}$	$Q_{NH_3}$
0	16.8	1.20	25.7	~0
<i>M</i> /5000	8.5	1.18	10.2	2.30
0	14.6	0.82	35.8	~0
<i>M</i> /1000	5.1	1.41	6.4	2.00

In muscle, too, glutamic acid causes an increase in oxygen uptake without influencing ammonia formation (D. M. Needham). This however is an effect different from that in kidney.

## 2. Disappearance of ammonia from kidney in the presence of glutamic acid.

If ammonium salts are added to guinea-pig or rabbit kidney in the presence of *l*(+)-glutamic acid, the ammonia disappears from the solution (Table III, Fig. 1). 11.79 mg. kidney, for instance, removed 95  $\mu$ l. of ammonia in 30 mins.,  $Q_{\text{NH}_3} \left[ \frac{\mu\text{l. NH}_3 \text{ used}}{\text{mg.} \times \text{hours}} \right]$  being -16.1. Similar figures were obtained with rabbit kidney (Table V). The rate of disappearance of ammonia is even higher than the rate of synthesis of urea in liver under average conditions.

Table III. Disappearance of ammonia from guinea-pig kidney.

11.79 mg. kidney in 2 ml. phosphate saline containing *M*/50 *l*(+)-glutamic acid and 166  $\mu$ l.  $\text{NH}_3$ ; 37.5°;  $\text{O}_2$ .

Time mins.	Ammonia present in 2 ml. $\mu$ l.	Ammonia used $\mu$ l.
0	166	—
30	71	95
60	14	152
90	0	166

Fig. 1. Disappearance of ammonia in the presence of *l*(+)-glutamic acid (guinea-pig kidney).

No ammonia disappears from kidney in the absence of *l*(+)-glutamic acid; in the presence of amino-acids such as *d*(-)-glutamic acid, aspartic acid,  $\beta$ -hydroxyglutamic acid and numerous others the concentration of added ammonia is either unchanged or increased on account of deamination. The only two nitrogenous substances which behave similarly to glutamic acid are proline and hydroxyproline. The metabolism of these two substances will be dealt with in the next paper of this series.

In the presence of lactate or pyruvate, small quantities of ammonia can be utilised by kidney as shown in Table IV; the amount however is only 5-8% of that which disappears in the presence of glutamic acid.

Table IV. *Disappearance of ammonia from guinea-pig kidney in the presence of lactate and pyruvate.*

Substrate added	mg. tissue	NH <sub>3</sub> per flask (μl.)		NH <sub>3</sub> used μl.	Q <sub>NH<sub>3</sub></sub>
		At start	After 60 min.		
dl-Lactate (M/50)	10.64	86	74.0	12.0	-1.13
Pyruvate (M/50)	10.32	86	73.9	12.1	-1.17

### 3. Formation of amide-nitrogen in kidney.

If the solution from which ammonia has disappeared in the presence of glutamic acid is heated for 5 min. with 5 % sulphuric acid, the ammonia appears again in the solution (Table V). Amino-acids or amino-purines do not split

Table V. *Disappearance of ammonia and formation of amide-nitrogen in kidney.*

Phosphate saline; M/50 l(+) - glutamic acid.

Tissue	Dry wt. of tissue mg.	NH <sub>3</sub> added μl.	Dura- tion of exp. mm.	NH <sub>3</sub> at end μl.	Change NH <sub>3</sub> μl.	Q <sub>NH<sub>3</sub></sub>	Amide-N found μl.	Q <sub>Amide-N</sub>
Guinea-pig kidney	11.79	166	30	71	- 95	- 16.1	124	+ 21.0
	18.82	202	20	21	- 181	- 28.8	191	+ 30.4
	7.66	232	60	38	- 194	- 25.3	222	+ 29.0
Rabbit kidney	15.00	232	60	53	- 179	- 12.0	187	+ 13.9
	9.33	224	80	70	- 154	- 12.4	186	+ 14.9
	9.87	218	60	25	- 193	- 19.5	236	+ 24.0

off ammonia when heated for 5 min. in dilute acid, whereas acid amides are hydrolysed by hot dilute acid [Sachsse, 1873]. Asparagine requires heating for one hour, whereas glutamine is completely hydrolysed within 5 min. by 5 % sulphuric acid at 100° (Table VI). We may therefore conclude that the kidney tissue has converted ammonium glutamate into glutamine.

The amount of glutamine formed is usually somewhat larger than the amount of ammonia which disappears (Table V). The source of the excess of amide-nitrogen is ammonia formed by deamination of the glutamic acid. Whilst one part of the added glutamic acid is deaminated, another part unites with the ammonia in the synthesis of glutamine.

Table VI. *Acid hydrolysis of acid amides.*

0.005 M amide heated with 5 % (final concentration) sulphuric acid at 100°. Calculated for complete splitting 112 μl. NH<sub>3</sub> per ml.

Amide	Time of heating min.	NH <sub>3</sub> formed (μl.) per 1 ml.	% splitting
Glutamine	2	91.5	82
	4	111.5	99.6
	8	113.0	100.9
	5	26.0	23.2
Asparagine	5	0	0
Urea	5	0	0

### 4. Formation of glutamine in various tissues.

In the kidneys of guinea-pig and rabbit synthesis of glutamine proceeds more rapidly than deamination of glutamic acid; thus no free ammonia but only glutamine accumulates in these kidneys after addition of glutamic acid

(Table VII). Kidneys of rat and sheep deaminate more quickly than they form glutamine, and ammonia and glutamine appear in the solution simultaneously. Added ammonia does not disappear in these cases, the tissue being already saturated with ammonia from deamination. On the other hand no amide-nitrogen is formed in the kidneys of pig, dog or cat if glutamic acid and ammonia are present.

Table VII. *Formation of glutamine in kidney cortex of various mammals.*

Tissue (kidney)	No ammonia added.			<i>M</i> /50 l (+)-glutamic acid		
	No glutamic acid added					
	$Q_{O_2}$	$Q_{NH_3}$	$Q_{Amide-N}$	$Q_{O_2}$	$Q_{NH_3}$	$Q_{Amide-N}$
Guinea-pig	14.5	0.98	0.20	38.0	0	6.36
Rabbit	13.8	0.37	1.38	24.6	0.40	2.92
Sheep	13.9	1.77	0.68	26.6	3.11	7.50
Rat	21.0	2.90	1.40	43.2	6.00	2.83
Pig	16.9	1.80	~0	21.7	2.23	~0
Cat	16.6	1.57	~0	24.4	2.74	~0
Dog	21.3	1.36	~0	27.2	2.69	~0
Pigeon	18.2	2.21	~0	26.4	4.40	~0

Thus the system which synthesises glutamine is not found in all kidneys, but it is found in the retina and central nervous system of all the vertebrates which have been investigated (various mammals, birds, tortoise, frog, trout (see

Table VIII. *Consumption of ammonia and formation of glutamine in brain cortex and retina.*

Solution: 3 ml. phosphate saline; *M*/50 l (-)-glutamic acid; *M*/30 glucose; 37.5°, unless otherwise stated.

Retina, tortoise (30°) ( <i>Testudo graeca</i> )	1.21	240	68.5	24.5	- 9.00	42.5	8.70
Brain, trout (30°)	22.4	60	127.0	95.0	- 1.44	33.0	1.47
Retina, trout (30°)	8.71	60	127.0	25.0	- 11.7	88.0	10.1

Table VIII)). The retina of warm-blooded animals forms about 6–10  $\mu$ l. of amide-nitrogen per mg. or 5–7 % of its own dry weight of glutamine per hour. In brain cortex the rate is about a third of that in retina.

Whilst in kidney, as mentioned earlier, the amount of amide-nitrogen formed is usually slightly higher than the amount of ammonia consumed, in brain and in retina the amount of ammonia which disappears is often greater than the amount of amide-nitrogen found. This will be further studied in section 10.

No formation of amide-nitrogen from ammonium glutamate was detectable in the following tissues of the guinea-pig: kidney medulla, liver, spleen, testis, placenta, chorion, muscle, heart, salivary glands, pancreas, white matter of brain, red blood cells, small intestine; or in Jensen rat sarcoma, mice Crocker tumour, fowl tumour and pigeon blood.

### 5. Some properties of the glutamine-synthesising system.

A. Influence of  $p_{\text{H}}$ . The optimum  $p_{\text{H}}$  for the synthesis of glutamine in guinea-pig kidney is 7.2–7.4, as shown in Table IX and Fig. 2.

Table IX. Influence of  $p_{\text{H}}$  on the synthesis of glutamine.

Guinea-pig kidney; 37.5°.  $p_{\text{H}}$  varied by varying the concentration of bicarbonate in the saline and the concentration of  $\text{CO}_2$  in the gas mixture. Various concentrations of bicarbonate were obtained by mixing 1.3% bicarbonate with bicarbonate-free saline.  $M/50$  L(+) -glutamic acid. Ammonium chloride:  $2.72 \times 10^{-3} M$ ; 3 ml. solution for each flask.

Conc. of bicarbonate ( $M$ )	0.155	0.125	0.0950	0.0339	0.0136	0.00358	0.00358
Percentage of $\text{CO}_2$ in the gas mixture	2.5	5.0	5.0	5.0	5.0	5.0	20.0
$p_{\text{H}}$	8.58	8.19	8.07	7.62	7.22	6.64	6.04
mg. of kidney cortex	7.23	7.71	9.20	8.24	5.57	12.83	10.21
$\text{NH}_3$ at the beginning ( $\mu$ l. per flask)	201.0	201.0	201.0	201.0	201.0	201.0	201.0
$\text{NH}_3$ found after 40 min. ( $\mu$ l.)	204.0	148.5	114.0	105.5	132.0	100.0	172.0
$\text{NH}_3$ used ( $\mu$ l.)	3.0	-53.5	-87.0	-95.5	-69.0	-101.0	-29.0
$Q_{\text{NH}_3}$	~0.0	-10.4	-14.2	-17.4	-18.6	-11.8	-4.25
Amide-N found after 40 min. ( $\mu$ l.)	38.0	56.5	83.6	123.0	84.2	114.5	42.4
$Q_{\text{Amide-N}}$	7.9	11.0	13.6	22.4	22.6	13.4	6.2

Fig. 2. Influence of  $p_{\text{H}}$  on the synthesis of glutamine (guinea-pig kidney).

B. *Concentration of glutamic acid.* It is only when the solution contains excess of glutamic acid that ammonia reacts completely to form glutamine in kidney (Tables III and X). In brain or retina however no excess of glutamic acid is

Table X. *Influence of the concentration of l(+)-glutamic acid on the synthesis of glutamine.*

Guinea-pig kidney; 3 ml. phosphate saline: initial concentration of ammonium chloride 0.00148 M; amount of tissue 4–6 mg.; time 80 min.; 37.5°.

Concentration of l(+)-glutamic acid M	$Q_{O_2}$	$Q_{NH_3}$	$Q_{Amide-N}$
0	11.5	+ 0.36	1.67
0.0033	29.1	- 10.9	8.80
0.0066	28.7	- 16.0	15.4
0.022	44.0	- 24.2	26.0

necessary; if glutamic acid is added in small quantities and ammonia in excess, practically the whole of the glutamic acid is converted into glutamine. The amount of ammonia which disappears is approximately equivalent to the amount of glutamic acid present (Table XI).

Table XI. *Disappearance of ammonia in the presence of small amounts of l(+)-glutamic acid and excess of ammonia.*

Sheep retina (about 30 mg. per experiment); 37.5°; 2 hours;  
bicarbonate saline with 0.3% glucose; 5%  $CO_2$  in  $O_2$ .

Glutamic acid added $\mu$ l.	NH <sub>3</sub> in the liquid ( $\mu$ l.)		Change in NH <sub>3</sub> $\mu$ l.	Total NH <sub>3</sub> consumed by the tissue, corrected for blank $\mu$ l.	Amide-N found $\mu$ l.
	Initial	Final			
112	350	264	- 86	104	72
224	350	140	- 210	228	158
0	0	18	+ 18	--	2

C. *Influence of glucose.* The synthesis of glutamine in kidney is unaffected by glucose; in retina and brain however the rate of synthesis is very small in the absence of glucose. All the figures recorded in Table VIII were obtained in glucose-containing saline. Table XII shows some examples of the effect of glucose on the rate of glutamine synthesis in brain and retina.

Table XII. *Influence of glucose on the rate of disappearance of ammonia and rate of synthesis of glutamine.*

Experimental conditions as in Table VIII.

Tissue	No glucose		M/50 glucose	
	$Q_{NH_3}$	$Q_{Amide-N}$	$Q_{NH_3}$	$Q_{Amide-N}$
Retina, sheep	-0.46	+0.58	-6.03	+3.67
Brain, rat	-0.70	+1.40	-3.75	+3.72

D. *Grinding and extracting.* Ground kidney, suspended in 10 vols. of saline, does not synthesise glutamine. The synthesis is bound up with the structure of the cell, as might be expected since it requires energy.

E. *Relation to energy-giving reactions.* In kidney, respiration is practically the only reaction which can provide energy for endothermic reactions. It would

therefore be expected that inhibition of respiration would inhibit the synthesis of glutamine. This is actually the case. Under strictly anaerobic conditions, glutamine is not synthesised in kidney. Hydrocyanic acid inhibits the glutamine synthesis approximately in the same degree as it inhibits respiration (Table XIII).

Table XIII. *Inhibition by hydrocyanic acid.*

$10^{-4}$	-17.6	-5.66	6.65
$10^{-3}$	-4.30	-3.1	2.1

Unlike kidney cortex, brain and retina possess a second very active energy-providing system, namely lactic acid fermentation. It seemed of interest to test whether lactic acid fermentation can provide the energy for the synthesis of glutamine. 30.7 mg. of brain cortex were shaken for 130 min. in bicarbonate saline solution ( $0.027 M$  bicarbonate,  $0.02 M$   $l(+)$ -glutamic acid,  $0.002 M$  ammonium chloride,  $0.002 M$  pyruvic acid, 5%  $CO_2$  in  $N_2$ ) under strictly anaerobic conditions (wet yellow phosphorus in the inner cup of the vessel). After 130 min.  $16 \mu l$ . amide-nitrogen were found in the solution. This corresponded approximately to the preformed amide-nitrogen so that no synthesis of glutamine had occurred.

Retinae of pig and pigeon however synthesise glutamine under strictly anaerobic conditions (Table XIV). In pig retina the rate of synthesis is smaller

Table XIV. *Synthesis of glutamine in retina under anaerobic conditions.*

$M/50$   $l(+)$ -glutamic acid; 0.4% glucose;  $M/500$  pyruvate;  $M/40$  bicarbonate;

anaerobically than aerobically whilst in pigeon retina no appreciable difference is found in oxygen and nitrogen. The respiration of pigeon retina is extremely small; in bicarbonate saline or serum there is no measurable respiration [Krebs, 1927] (for technical reasons) whilst in phosphate saline a respiration of 7.5 is found (Table XV). The glycolysis ( $Q_M$ ) of pigeon retina amounts to about 150. Pigeon

retina obtains its energy preferentially from the anaerobic lactic acid fermentation and therefore it is not surprising that the synthesis of glutamine, as an energy-requiring reaction, does not depend on the presence of oxygen. Accordingly  $10^{-3} M$  HCN does not inhibit the formation of glutamine in pigeon retina.

F. *Inhibition by d(-)-glutamic acid.* If *d(-)-glutamic acid* and ammonia are added to kidney, no glutamine is formed. Racemic glutamic acid gives about half the yield of glutamine and half the increase in respiration given by *l(+)-glutamic acid* under the same conditions (Table XVI). This halving effect

<i>l(+)-Glutamic acid</i> ( <i>M</i> /150); $NH_4Cl$ ( <i>M</i> /370)	-28.7	-16.0	15.4
$NH_4Cl$ ( <i>M</i> /370)	-11.5	+0.4	1.7
<i>d(-)-Glutamic acid</i> ( <i>M</i> /150), $NH_4Cl$ ( <i>M</i> /370)	-12.5	+1.0	1.3

is due to specific inhibition of the glutamine-synthesising system by *d(-)-glutamic acid*. Addition of *d(-)-glutamic acid* to *l(+)-glutamic acid* has the same result as addition of *dl-glutamic acid*. The figures in Table XVI show that it is not the absolute concentration of *d(-)-glutamic acid* which determines the degree of inhibition but the ratio  $\frac{\text{concentration of } l(+)\text{-glutamic acid}}{\text{concentration of } d(-)\text{-glutamic acid}}$ . For instance *M*/150 *d(-)-glutamic acid* inhibits the amide-nitrogen formation by 50% if the concentration of the antipode is *M*/150, but only by 34% if the concentration of the antipode is *M*/50.

The inhibition by *d(-)-glutamic acid* can be explained by the assumption that both isomerides combine with the enzyme and that the affinities of the enzyme for both are equal; only *l(+)-glutamic acid* however reacts to form glutamine.

Neither  $\alpha$ -ketoglutaric acid, *dl-* and *l(-)-aspartic acid* nor *dl-alanine* influences the rate of glutamine formation. A slight inhibition is found when synthetic *dl-β-hydroxyglutamic acid* is added (Table XVII).

Table XVII. *Inhibition of the glutamine synthesis by dl-β-hydroxyglutamic acid.*

Guinea-pig kidney, phosphate saline, 37.5°.

Substrates added (final concentrations)	$Q_{O_2}$	$Q_{NH_3}$	$Q_{Amide-N}$
<i>l(+)-Glutamic acid</i> ( <i>M</i> /60), $NH_4Cl$ ( <i>M</i> /184)	28.9	-25.3	+26.5
<i>l(+)-Glutamic acid</i> ( <i>M</i> /60), $NH_4Cl$ ( <i>M</i> /184) + <i>dl-β-hydroxyglutamic acid</i> ( <i>M</i> /60)	26.7	-19.3	+16.9

G. *Bicarbonate and phosphate buffers.* Varying the concentration of bicarbonate between *M*/40 and *M*/270, or replacing bicarbonate with phosphate does

not essentially influence the rate of glutamine synthesis in guinea-pig kidney if the  $p_H$  is kept constant (Table XVIII).

Table XVIII. *Synthesis of glutamine in bicarbonate and phosphate buffers.*

### 6. Enzymic hydrolysis of glutamine into glutamic acid and ammonia.

If glutamine is added to extracts of brain, retina or kidney, the reaction described in the previous sections is reversed and glutamine is split into glutamic acid and ammonia (Table XIX). This reaction is not dependent on the cell structure and can be conveniently investigated in aqueous tissue extracts.

Table XIX. *Activities of asparaginase and glutaminase in kidney and liver extracts of rabbit and guinea-pig.*

Each test-tube contains 4.5 ml. veronal buffer ( $p_H$  7.7;  $M$  10), 1.5 ml. water, 0.5 ml.  $M/5$  substrate (asparagine or glutamine) and 1 ml. tissue extract (1 part fresh tissue ground extracted with 10 parts water, centrifuged and supernatant fluid used), 1 hour;  $37.5^\circ$ .

"	Glutamine	368	332
"	—	36	—
Guinea-pig kidney	Asparagine	95	51
"	Glutamine	225	181
"	—	44	—

Enzymic hydrolysis of glutamine was observed by Hunter and Geddes [1928] and by Grassmann and Mayr [1933] in yeast extracts (see also Luck [1924]) when they were studying the specificity of asparaginase (which hydrolyses asparagine to aspartic acid and ammonia). These authors reached no conclusion as to whether glutamine and asparagine are split by one and the same enzyme. It can be shown however that there is a specific "glutaminase" in some tissues: rabbit kidney splits glutamine rapidly but hydrolyses asparagine very slowly (Table XIX). Rabbit liver on the other hand splits glutamine about five times more slowly than asparagine (under the same conditions). The ratio  $\frac{\text{activity of asparaginase}}{\text{activity of glutaminase}}$  is about 1/100 for rabbit kidney and about 4 for rabbit liver extracts. If one enzyme were responsible for the breakdown of both amides, the above ratio should be constant. It follows from these experiments that glutaminase is a specific enzyme.

When glutamine is converted into ammonia and glutamic acid apparent amino-nitrogen must disappear from the solution, since 90% of the total

nitrogen of glutamine reacts in Van Slyke's method (the reaction time being 5 min.). Hence the disappearance of amino-nitrogen as determined by Van Slyke's method should amount to 80% of the ammonia formed. The experimental result agrees with the predicted figure within the limits of error: 0.6 ml. *M*/10 glutamine was mixed with 0.9 ml. brain extract (rat brain extracted with 10 vols. water) and 0.15 ml. *M* sodium bicarbonate. Immediately after mixing 785  $\mu$ l. amino-nitrogen were found in 0.5 ml. solution. After one hour's incubation (37.5°) 341  $\mu$ l. ammonia were found in 0.5 ml. Another 0.5 ml. was mixed with 1 ml. borate buffer,  $p_H$  9.5, and evaporated *in vacuo* to 0.5 ml. in order to remove ammonia. The amount of amino-nitrogen found in this solution was 480  $\mu$ l. Thus 305  $\mu$ l. amino-nitrogen had disappeared, whilst 341  $\mu$ l. ammonia appeared. The loss of amino-nitrogen is somewhat higher than calculated (89% found, 80% calculated). This might be expected since slight decomposition of glutamine during the evaporation, necessary for the removal of ammonia, is unavoidable.

Glutamine, heated (100°) in neutral solution, yields pyrrolidonecarboxylic acid and ammonia [Chibnall and Westall, 1932]. In this case two amino-groups disappear for one equivalent of ammonia formed; thus enzymic splitting and neutral heat hydrolysis yield different products.

#### 7. Some properties of glutaminase.

A. *Specificity*. As mentioned in the previous paragraph glutaminase does not hydrolyse asparagine. Phenacetylglutamine and benzoylglutamine, kindly supplied by Dr N. W. Pirie, are not attacked by kidney or brain extracts. Glutamine peptides (glutaminylglycine and glutaminylglutamic acid) which Prof. Chibnall kindly gave me did not yield ammonia in the presence of rat brain extracts. *iso*Glutamine (also from Prof. Chibnall) is slowly hydrolysed, the velocity being only a few % of the rate of splitting of glutamine (Table XX).

Table XX. *Action of rat brain extract on glutamine derivatives.*

Brain extract: one part brain ground with 10 parts *M*/10  $\text{NaHCO}_3$ . Each test-tube contained 0.5 ml. extract and 0.3 ml. *M*/10 neutralised substrate solution.  $p_H$  8.5. Blank controls for brain extract and for the substrates. Incubation 2 hours; 37.5°.

Glutaminylglycine	12
Glutaminylglutamic acid	0

B. *Inhibition by glutamic acid*. A peculiar phenomenon is observed when the course of hydrolysis of glutamine is followed in extracts of kidney, brain or retina. The hydrolysis starts with a high velocity (Table XXI, Fig. 3), but the rate soon falls off. Initially 156  $\mu$ l. ammonia were formed per mg. dry kidney per hour, but when only one-sixth of the total amount of glutamine was split the velocity fell to one-third of the initial rate, and when half of the substrate was decomposed the velocity was about 6  $\mu$ l. per mg. per hour, that is 3.8% of the initial rate. This decrease of activity is not due to destruction of the enzyme, since addition of fresh extracts does not restore the initial rate, but increases

Table XXI. *Course of action of glutaminase.*

5 ml. phosphate buffer;  $p_H$  7.8; 1 ml. pig kidney extract (1 part minced kidney cortex extracted with 4 vols. of water, centrifuged; 3 ml. glutamine ( $M/20$ ); 1 ml. water. the rate only in proportion to the enzyme concentration. The diminishing activity is due to inhibition of glutaminase by the glutamic acid formed in the hydrolysis.

This inhibition of glutaminase by glutamic acid is shown directly in Table XXII.  $2.5 \times 10^{-2} M$  *l*(+)-glutamic acid produces 98 % inhibition of the

Control	48	—

splitting of  $0.87 \times 10^{-2} M$  glutamine. Both optical isomerides of glutamic acid are equally active as inhibitors. This inhibition is not due to thermodynamic equilibrium between glutamine and ammonium glutamate; the equilibrium of the reaction lies at practically complete hydrolysis of the amide (in physiological solutions). This is shown by the facts that the splitting of glutamine

goes to completion even in the presence of glutamic acid (though extremely slowly), and that no trace of glutamine is formed from glutamic acid and added ammonia in the presence of glutaminase.

The inhibition of glutaminase by glutamic acid could be explained however by a competition of glutamine and glutamic acid for the enzyme. Competitive inhibitions by compounds which are chemically similar to the substrate are known (*e.g.* in the cases of xanthine oxidase and of sucrase), but asparaginase is not inhibited by aspartic acid. It is remarkable that the inhibition of glutamic acid requires very small amounts of glutamic acid, indicating that the affinity of glutamic acid for the enzyme is much greater than that of glutamine. From the experiment given in Table XXI and Fig. 3, it may be calculated that the rate falls to 50% of the initial rate when 18–20% of the glutamine is hydrolysed. Hence the enzyme is equally distributed between glutamine and glutamic acid if the ratio of concentrations of glutamine to glutamic acid is 4 to 1.

The inhibitory action of glutamic acid is specific except that *dl*- $\beta$ -hydroxyglutamic acid causes a slight inhibition (Table XXIII). Other amino-acids, or glutathione or  $\alpha$ -ketoglutaric acid have no effect. The fact that *d*(-)-glutamic acid and *dl*- $\beta$ -hydroxyglutamic acid inhibit glutamine synthesis and

Table XXIII. *Inhibition of glutaminase by dl- $\beta$ -hydroxyglutamic acid.*

centration on the initial velocity of hydrolysis. As expected from the preceding experiments an increase of the concentration of glutamine increases the velocity of the hydrolysis considerably.

F. *Influence of  $p_H$ .* 3 g. guinea-pig brain were ground with sand and extracted with 24 ml. water. 1 ml. of the centrifuged extract was mixed with 0.8 ml.  $M/10$  glutamine solution and 0.2 ml. buffer. The flasks were incubated for 40 min. at  $37.5^\circ$ ; ammonia was then determined. Blanks were carried out to measure the ammonia formation in the absence of added glutamine. The blank was found to be independent of  $p_H$ ; it amounted to  $11 \mu\text{l. NH}_3$  per flask. The results are given in Table XXVII and Fig. 4. Similar experiments were carried out with kidney and liver extracts. Sheep kidney was extracted with 4 vols. of water. The liver extract was prepared by extracting guinea-pig liver with five parts of water. The results are also recorded in Table XXVII.

Owing to the complications in the kinetics before mentioned the curves in Fig. 4 give only an approximate picture of the influence of  $p_H$  on glutaminase. The optimum of brain glutaminase lies between  $p_H$  8 and 9. The curves for kidney, liver and brain glutaminase are not identical. In the next paragraph further evidence will be adduced showing that the splitting of glutamine in various tissues is due to different "glutaminases".

G. *Glutaminase in various tissues. Existence of different glutaminases.* Glutaminase is found in those tissues in which the synthesis of glutamine occurs, but it is also found in some tissues which do not synthesise glutamine, for instance in spleen and liver of the guinea-pig and in pig kidney. Table XXVIII shows the relative activities of extracts from various tissues.

The most characteristic property of glutaminase found so far is the inhibition of the enzyme by glutamic acid. But this inhibition is not found in all tissue extracts in which a glutaminase is found. Guinea-pig liver for instance hydrolyses glutamine rapidly, but glutamic acid does not inhibit the reaction (Table XXVIII). This proves again (see the preceding paragraph) that the glutamine-splitting enzyme in guinea-pig liver is different from the enzyme in kidney, brain or retina. There are at least two types of glutaminase distinguishable by their  $p_H$  optima and their inhibitions by glutamic acid ("brain type" and "liver type"). Some tissues, for instance rat kidney, seem to contain both types of glutaminase, since the splitting of glutamine is partly inhibited by glutamic acid and the  $p_H$  curves show two maxima.

The second glutaminase ("liver type"), too, is different from asparaginase. Guinea-pig liver splits both amides, asparagine and glutamine, and the rates of splitting are of the same order of magnitude. But blood serum from guinea-pig does not attack glutamine whereas it splits asparagine rapidly [Clementi, 1922]: 1 ml. serum hydrolyses up to 30 mg. asparagine per hour ( $p_H$  7.4, 37.5°). Asparaginase is thus found in nature separately from the enzymes which split glutamine. This proves that asparaginase is not concerned in the splitting of glutamine.

#### 8. *Glutamine as precursor of ammonia in tissues.*

Most animal tissues are capable of forming ammonia by anaerobic reactions when incubated at body temperature. The rate of ammonia formation is often much greater after destruction of the cells. Thus red blood corpuscles of birds form hardly any ammonia as long as the cells are intact and the medium contains oxygen and sugar; but laked cells, or cells which have been deprived of their substrates for energy-giving reactions, form ammonia. A difference between intact and ground tissues as regards ammonia formation has been demonstrated for muscle by Embden *et al.* [1928] and by Parnas and Mozołowsky [1927], for brain by Schwarz and Diebold [1932] and by Riebeling [1934]. I find it also in kidney, testicle and intestinal wall.

The precursors of the ammonia derived from anaerobic sources in tissues are not all known. In some tissues, adenylic acid seems to be the chief precursor. In blood (see Klisiecki and Heller [1935]), brain and other tissues the amount of adenylic acid is too small to account for the total ammonia formed.

Other possible sources of ammonia formed anaerobically are asparagine and glutamine. I have used the inhibitory effect of glutamic acid on glutaminase to decide whether some of the ammonia formed in mashed tissue is due to the action of glutaminase ("brain type"). Brain, retina and kidney (pig and guinea-pig) were divided into two equal fractions; the first fraction was ground with water, the second with  $M/50$   $l(+)$ -glutamic acid. The same amount of ammonia was found however in each fraction after incubating the tissues and the extracts at 38° at  $p_H$  8.5 or 7.4. Hence we may conclude that glutaminase ("brain type") is not concerned with spontaneous ammonia formation in the tissues examined.

#### 9. *Effect of $l(+)$ -glutamic acid on the formation of ammonia in brain and retina.*

Slices of brain tissue or retina, when suspended in saline, produce considerable amounts of ammonia (for references see Dickens and Greville [1933].  $l(+)$ -glutamic acid reduces the output of ammonia in brain and retina as shown in

Table XXIX. In some experiments no ammonia at all could be detected when *l*(+)-glutamic acid was present; but instead of ammonia amide-nitrogen was found. The sum of ammonia *plus* amide-nitrogen is approximately the same in

Table XXIX. *Formation of ammonia and amide-nitrogen in brain and retina in the presence of l(+)-glutamic acid.*

Tissue	Substrates added	$Q_{\text{NH}_3}$	$Q_{\text{Amide-N}}$	$Q_{\text{NH}_3} + Q_{\text{Amide-N}}$

{ „	<i>M</i> /90 glucose - <i>M</i> /50 <i>l</i> (+)-glutamic acid	0.28	0.67	0.95

the presence as in the absence of *l*(+)-glutamic acid. Thus whilst glutamic acid causes a change in the ratio  $\frac{\text{ammonia}}{\text{amide-nitrogen}}$  it does not increase the sum ammonia *plus* amide-nitrogen. This is remarkable seeing that glutamic acid causes an increase in the oxygen uptake of brain and retina [Krebs, 1935].

The non-natural *d*(-)-glutamic acid does not inhibit the formation of ammonia in brain. This shows that the "inhibition" of ammonia formation by *l*(+)-glutamic acid is not due to inhibition of glutaminase, since glutaminase is equally affected by the stereoisomerides. The "inhibition" must be explained by the secondary disappearance of the ammonia through the synthesis of glutamine.

Warburg *et al.* [1924] and Dickens and Greville [1933] have found that slices of kidney, brain, and retina form less ammonia in the presence of glucose than in glucose-free saline. But glucose, unlike glutamic acid does not increase the yield of amide-nitrogen (see the last experiment in Table XXIX).

#### 10. *The fate of glutamine in brain and retina.*

When the amount of amide-nitrogen which is formed in brain or retina is compared with the amount of ammonia which has disappeared (see Table VIII) it will be seen that, in some cases, more ammonia is used than amide-nitrogen is found. The deficit is very considerable in some experiments on retina. Two explanations for this deficit suggest themselves: either ammonia may be used for another reaction, or a part of the glutamine formed may disappear by a secondary reaction. The following experiments favour the second explanation.

Retina was suspended in glutamine-containing saline at  $p_{\text{H}}$  7.4. After incubating for one or two hours the tissue was well washed and the washings were

added to the experimental solution. Ammonia and amide-nitrogen were then determined in the solution. Only a small amount of ammonia was found, hardly more than in controls to which no glutamine was added. The amide-nitrogen on the other hand was considerably decreased (Table XXX). The sum of ammonia

Table XXX. *Disappearance of glutamine from retina.*

For each experiment 3 ml. bicarbonate saline, 0.4% glucose, 5% CO<sub>2</sub> in O<sub>2</sub>; 35.0°. The deficit shown in the last column has not been corrected for blanks and therefore represents a minimum value.

Animal	Tissue mg.	Glutamine added μl.	Time min.	NH <sub>3</sub> formed μl.	Amide-N found μl.	Deficit μl.
Sheep	33.95	162	100	3.5	122	36.5
"	24.48	610	120	22.0	544	44.0
"	16.54	212	120	29.0	132	51.0
"	30.0	308	120	16.5	154	137.0
Pigeon	7.0	141	120	12.0	96	33.0

and amide-nitrogen as compared with the added glutamine shows a marked deficit. These results indicate that the tissue utilises glutamine but not by splitting it into glutamic acid and ammonia. The nature of the products of the conversion of glutamine remains to be investigated.

### 11. *Some experimental details.*

The methods used in this paper—tissue slices, manometric procedure, determination of ammonia—were essentially the same as in the preceding paper [Krebs, 1935]. Certain additional details are given in this section.

*Glutamine* was prepared according to Schultze and Winterstein from sugar beet or mangold wurzels [see Vickery *et al.*, 1935]. In the beginning of this investigation, I had at my disposal a large sample prepared by Dr N. W. Pirie.

*Preparation of dl-glutamic acid.* 50 g. of l(+) -glutamic acid were heated in an oil-bath for 50 min. at 170–180° and for 50 min. at 220°. The dl-pyrrolidonecarboxylic acid formed was hydrolysed with 3 times its weight of concentrated hydrochloric acid for 4 hours at boiling temperature. The dl-glutamic acid was then isolated in the usual way. Yield 17 g. recrystallised dl-glutamic acid.  $[\alpha]_D + 1.84^\circ$  (in 2N HCl); amino-N 9.85%. This procedure is the method of Abderhalden and Kautsch [1910], except for the time of heating. The racemisation was very incomplete when the directions of Abderhalden and Kautsch were followed.

*Preparation of d(-) -glutamic acid.* 10 g. dl-glutamic acid were fermented with yeast according to Ehrlich [1914]. Yield 1.6 g. recrystallised d(-) -glutamic acid.  $[\alpha]_D - 34.6^\circ$  (0.1936 g. in 20 ml. 2N HCl). Amino-N 9.43%.

*Solutions.* "Phosphate saline" and "bicarbonate saline" were made up as described previously [Krebs, 1933, 1]; 2–4 ml. were used for each flask. All substrate solutions which were added to the experimental fluid were neutralised with sodium hydroxide before they were added; ammonia was added as ammonium chloride.

*Determination of amide-nitrogen (glutamine).* The free ammonia was removed and determined in the apparatus of Parnas and Heller. The ammonia-free solution was transferred to a test-tube, neutralised with 14N sulphuric acid and mixed with one-tenth volume of 30% trichloroacetic acid. The volume of the fluid was now measured. The solution was filtered and an aliquot part of the filtrate was acidified with one-tenth of its volume of 50% sulphuric acid, heated for 5 min. in a boiling water-bath (see Table VI), cooled and made alkaline with 50% sodium hydroxide (thymolphthalein). Ammonia was then determined in Parnas's apparatus. Known amounts of glutamine were recovered by this method with an accuracy of 1–2%.

*Blanks.* Since glutamine solutions decompose spontaneously (though at a very slow rate), blanks were carried out in all experiments on the enzymic hydrolysis of glutamine to measure the spontaneous decomposition. Between pH 7 and 9 about 0.2–0.4% of the glutamine dissolved

decomposed in 1 hour at 38° as determined by ammonia formation. This figure includes the hydrolysis which may occur during the determination of ammonia.

*Tissue extracts* were made by grinding the tissue with sand and water and centrifuging. The supernatant fluid was used as "extract".

*Units.* In order to make the metabolic changes comparable with respiration all substances are expressed in terms of gas volumes. 17 mg.  $\text{NH}_3$ , or 14 mg. amide-N, or 14 mg. amino-N are taken as equivalent to 22400  $\mu\text{l}$ . at N.T.P.

## 12. Discussion.

A. *Reversibility of the glutamine synthesis.* The synthesis of glutamine in tissues can be reversed *in vitro*, for instance by changing the  $p_{\text{H}}$ . However, two facts indicate that the synthesis of glutamine is practically not reversed in the living cell. (1) The hydrolysis occurs in practice only outside the physiological range of  $p_{\text{H}}$ . (2) Glutamine disappears from brain or retina without forming ammonia. Thus there appears to be a cycle of ammonia in nervous tissue in which the conversion of ammonium glutamate into glutamine is one step. Nothing is known about the other stages.

B. *Physiological significance of glutaminase in brain and retina.* In a previous section (7 B) it has been shown that one and the same enzyme is probably concerned in the synthesis and the hydrolysis of glutamine in kidney, brain and retina. In the preceding paragraph it is suggested that the glutaminase found in extracts of these tissues is concerned *in vivo* with the synthesis only. It may well be that several hydrolysing enzymes found in tissue extracts are only components of synthesising systems. For instance hippuricase (histozym), or proteolytic and lipolytic enzymes are found in extracts of those tissues known to perform the respective syntheses *in vivo*.

C. *Glutamine synthesis and energy-giving reactions.* If the energy-giving reactions are inhibited (section 5 E) synthesis of glutamine ceases. This makes it evident that the system which synthesises glutamine consists of glutaminase and of an additional factor concerned with the transmission of energy. The transmission of energy results in a change in the thermodynamic equilibrium between ammonium glutamate and glutamine in favour of the latter. If this occurs the enzyme catalyses the attainment of the new equilibrium.

D. *Significance of the "glutamine system".* Nothing definite is known at present about the physiological function of the glutamine synthesis. Certain experiments suggest a connection between the system and the energy-giving reactions: *l*(+)-glutamic acid is the only amino-acid which increases respiration in brain and retina; unlike other amino-acids it inhibits anaerobic lactic acid fermentation. These experiments will be described in a later paper.

## SUMMARY.

1. Brain cortex and retina of vertebrates and kidney of rabbit and guinea-pig convert ammonium glutamate into glutamine. Under optimum conditions, kidney synthesises 10–20 % of its dry weight of glutamine per hour, retina 5–7 %, brain cortex 1–2 % (37.5°).

2. The synthesis of glutamine is an endothermic reaction and therefore depends on energy-giving reactions. Respiration supplies the energy in kidney and brain. In retina the energy can be derived from anaerobic lactic acid fermentation.

3. Extracts from those tissues which synthesise glutamine contain a specific enzyme which hydrolyses glutamine to ammonium glutamate ("glutaminase").

4. The synthesis of glutamine and the hydrolysis of glutamine are specifically inhibited by the non-natural *d*(-)-glutamic acid.

5. Some properties of glutaminase are described. Characteristic is the specific inhibition by glutamic acid.

6. Liver of mammals (pig, guinea-pig, rat) contains a glutamine-splitting enzyme which is not inhibited by glutamic acid and shows a  $p_H$  optimum different from the optimum of glutaminase from brain, kidney and retina. Both glutaminases ("brain type" and "liver type") are distinct from asparaginase.

This work was made possible by grants from the Rockefeller foundation and the Ella Sachs Plotz foundation.

I wish to express my thanks to Sir F. G. Hopkins for his interest and help; to Prof. Chibnall for samples of isoglutamine and glutamine peptides; to Prof. Harington for a sample of *dl*- $\beta$ -hydroxyglutamic acid; to Dr Pirie for samples of glutamine, benzoylglutamine and phenacetylglutamine, and to Mr V. H. Booth for his help in preparing the manuscript.

# CCXXXI. THE PERMEATION OF ERYTHROCYTES BY CATIONS.

By MONTAGUE MAIZELS.

*From the Department of Pathology, University College Hospital.*

*(Received July 1st, 1935.)*

WHEN erythrocytes are suspended in salt solutions, the amount of anion permeating varies with the external  $p_H$ . If acid is added to the external phase, then hydrogen ions and anions penetrate the cell membrane freely. If the penetration of cations like sodium and potassium were also rapid, then the amount of anion penetrating erythrocytes would vary not only with the external  $p_H$  but also with the external salt concentration. It is found, however, that when human erythrocytes are suspended in salt solution at constant  $p_H$ , the amount of permeating anion changes only slightly with considerable variations in the external salt concentration [Maizels, 1934]. In view of these observations it may be concluded that human erythrocytes are not readily permeated by cations, and that the penetration of chloride is prevented by the electrostatic attraction of the non-penetrating cation.

Whilst, however, observations on the relative impermeability of erythrocytes to cations have been numerous, there has been a lack of agreement between the findings of various investigators. These disagreements arise partly from the different techniques used and partly from the fact that the cells of different animals have been employed. For this reason the permeability of erythrocytes to cations has been re-examined: in the present investigation experiments have been limited to human cells, and changes in the potassium content have been measured after the cells have been suspended in solutions of sodium chloride, potassium chloride and glucose.

Gürber [1895] originally noticed the impermeability of erythrocytes to sodium and potassium, but Hamburger and Buba [1910], using ox corpuscles, observed that cations passed across the cell membrane on changing the carbon dioxide tension of the blood, or on altering the salt concentration of the serum. Ashby [1924], using human cells, found considerable changes in the cation of human erythrocytes suspended in 10 vols. of salt solution and incubated for one or more days. The  $p_H$  of the original salt solution was 7.4, but the  $p_H$  of the fluid after mixing with blood is not given. In any case cation leakage occurring after the lapse of many hours is rather a stringent criterion of cell permeability, for the integrity of the cell is unlikely to be maintained under these circumstances; and whilst one may agree with Ashby that partial haemolysis is clear evidence of cell damage, it is equally clear that some trauma must have existed before haemolysis became apparent.

Wakeman *et al.* [1927] were unable to confirm Hamburger's observations, for they detected no passage of cation in or out of human erythrocytes on adding to the serum either salts or water. These writers limited loss of  $CO_2$  from their preparations by saturating with  $CO_2$  (at a pressure of 40 mm. in air). Mond [1928] found that when the erythrocytes of oxen or swine were suspended in salt solutions cation permeation only occurred at  $p_H > 8$  to 8.3. Kerr [1929] found that the centrifuged erythrocytes of man, dog, sheep and ox, after 2 hours'

suspension in saline wash-fluid were all permeable to cation, but that permeability was greatly decreased when a high proportion of serum was added to the wash-fluid. Davson [1934] used a suspension of equal parts of ox corpuscles and salt solution and found a considerable and rapid permeation of cation which was unaffected by the presence of serum—indeed a considerable decrease of cell potassium occurred when the cells were left in contact with their own serum *in vitro*.

It follows from the work of Mond that in any investigation of cell permeability the  $p_H$  of the system should be known, and this is not the case with the experiments of Ashby, Kerr and Davson. Indeed it is probable that as a result of exposure to air, defibrination *etc.*, loss of  $CO_2$  from the cells will render these definitely alkaline and that this alkalinity will be imparted to the wash-fluid, thus increasing cell permeability. Any increase in the  $p_H$  of the wash-fluid is likely to be the more marked when its volume is not great compared with the volume of the suspended cells. Under these circumstances also the composition of the wash-fluid will be materially altered should cation permeation occur. In the present investigation a small quantity of cells was suspended in 70 vols. of solution; in this way changes in the reaction and composition of the wash-fluid were limited and in addition cells remained in contact with the suspending solution without constant agitation of the system. Further, as the cells were spun down into narrow capillaries, the amount of intercellular fluid was minimum.

#### METHOD.

Heparinised blood is centrifuged for 30 min. in tubes drawn out into sealed graduated and calibrated capillaries. The volume of erythrocytes (about 0.1 ml.) is accurately measured, the supernatant plasma removed and the cells suspended for a given time in 7 ml. of the test fluid. The suspension is then centrifuged, the new volume of the erythrocytes measured and the  $p_H$  of the supernatant fluid estimated [Maizels, 1934]. This fluid is then discarded and the centrifuge tube carefully washed with distilled water down as far as the upper face of the erythrocyte column. The cells are laked in about 2.5 ml. of water, 0.3 ml. of sodium tungstate (10 %) and 0.3 ml. of  $2/3N$   $H_2SO_4$  are added and the volume made up to 4 ml. After centrifuging, 1 ml. of the protein-free fluid is placed in a cylindrical centrifuge tube ( $9 \times 1$  cm.) the last centimetre of which tapers to a point. 1 ml. of sodium cobaltinitrite solution is added and after 16 hours the deposit of potassium cobaltinitrite is centrifuged down. All but 0.2 ml. of the supernatant fluid is removed and the tube almost filled with distilled water, at first added drop by drop so that the precipitate of potassium cobaltinitrite and its covering layer of sodium cobaltinitrite remain undisturbed. The latter is then removed with a capillary pipette and restored to the main bulk of wash-water in the tube (which is now pale amber in colour), after which the tube is again centrifuged. It is then left for 2 hours so that any sodium cobaltinitrite in the interstices of the packed precipitate may diffuse out. The precipitate is then twice washed after the fashion of the first washing, but after the final washing all the supernatant fluid is removed. The potassium cobaltinitrite is finally estimated by the method of Kramer and Tisdall [1921].

There are several possible objections to the above method. The composition of the potassium cobaltinitrite precipitate varies slightly, and it is therefore necessary to estimate the K content of a standard solution in the same way as that of the unknown in order to provide a factor with which the K in the unknown solution may be calculated. Again, it is conceivable that K present

in the protein precipitate might be greater or less than that in the protein-free fluid. Nevertheless potassium added to cells can be quantitatively recovered and the findings agree well with the results obtained on ashed cells within the limits of experimental error. Finally, potassium cobaltinitrite is not completely insoluble and it is important that the precipitate be not disturbed during the process of washing. The error in the method rarely exceeds  $\pm 3\%$  and is usually less than  $\pm 1.5\%$ . Duplicate experiments agree well and results are reproducible.

### RESULTS.

The findings in 53 normal cases were as follows: cell K averaged 107 m.eq. per litre of cells. In 7.5% of cases it was over 113 m.eq., in 79.5% between 96 and 113 m.eq., in 7.5% it was less than 96 m.eq., and in 5.5% less than 90 m.eq. The lowest figure was 87 m.eq., and the highest 119 m.eq.

#### *The cation content of cells suspended in solutions of potassium chloride or sodium chloride.*

*The effect of external concentration.* The concentration of K in the normal human erythrocyte is about 160 m.eq. per kg. of cell water. In the following experiments cells were suspended in KCl solutions varying in concentration from 100 to 514 m.eq., including 175 m.eq. which is only slightly hypertonic, and it will be seen (Table I) that though cell K increases slightly with external concentration, the total gain in K is relatively small over a wide range from 100 to 350 m.eq., and it is only when the external concentration becomes excessively high that the increase in cell K becomes more evident. Similarly, cell K is but little decreased when erythrocytes are placed in NaCl solutions of varying concentrations.

In Table I and in subsequent tables  $Q$  is the ratio of K present in unit volume of "original" cells resulting from suspension in salt solution, to that present before suspension. Thus

$$Q = K_f \times V / K_0,$$

where  $K_f$  is the K content per litre of suspended cells,  $K_0$  is the K content per litre of original cells, and  $V$  is the ratio of the volume after suspension to that before. Results are the mean of four observations.

It should be noted that  $Q$  indicates changes in the K content of the cells, or in other words changes in the actual amount of K passing across the erythrocyte membrane. It does not indicate changes in the K concentration of cells, that is the concentration per kg. of cell water. This latter value will be considered subsequently.

Table I.

(Cells 1 hour in salt solution at  $31^\circ$ ,  $p_H$  7.6.

External concentration m.eq.	Cells in KCl $Q$	Cells in NaCl $Q$
100	1.04	0.95
175	1.07	0.95
350	1.11	0.94
514	1.40	0.90

It might be thought that the apparent increases in cell K were due to the presence of a residue of the suspending fluid between the cells of the packed centrifuged deposit. If, however, a salt like potassium ferrocyanide (which penetrates erythrocytes extremely slowly) be added to the suspending fluid, it may be shown that not more than 1% by volume of the packed cells is occupied

by ferrocyanide, and this includes ferrocyanide in, on and between the cells. Hence intercellular salt solution can contribute but little to the changes in cell cation. In the case of the more dilute solutions, at least 70% of the small increase observed is due to the actual penetration of potassium, whilst with the very concentrated solution the real increase of cell K is at least 80% of the apparent increase.

*Temperature coefficient.* Temperature has little effect on the gain in total K of cells placed in potassium chloride solution, even when the external concentration is as great as 350 m.eq. But when the external concentration is very high indeed (514 m.eq.) the amount of K taken up by cells increases with temperature. Similarly, the loss of K from cells suspended in NaCl is practically unaffected by temperature.

Table II.

 Cells 1 hour in salt solution at  $p_H$  7.6.

Temp. °C.	Cells in KCl. External concentration			Cells in NaCl. External concentration		
	175 m.eq.	350 m.eq.	514 m.eq.	175 m.eq.	350 m.eq.	514 m.eq.
	Q	Q	Q	Q	Q	Q
10	1.06	1.09	1.25	0.95	—	0.93
24	1.07	1.09	1.31	0.95	0.95	0.90
31	1.07	1.11	1.41	0.95	0.94	0.89

*The effect of time.* In KCl solutions of moderate and high concentrations, the chief gain in K is almost immediate and during the next hour further increase is very slight. But if the external concentration is very high indeed the increase of cell K is more continuous and more marked. In NaCl solution a small loss of K occurs immediately, but thereafter cell K remains constant for at least 4 hours.

In Table III "0" minutes signifies that the cells are centrifuged immediately after suspension in the salt solution: the time is actually about 10 sec. *plus* an indeterminate period during which the cells are being centrifuged out of contact with the solution.

Table III.

 Cells in salt solution at 31°,  $p_H$  7.6.

Time min.	External KCl			External NaCl	
	175 m.eq.	350 m.eq.	514 m.eq.	350 m.eq.	514 m.eq.
	Q	Q	Q	Q	Q
"0"	1.06	1.08	1.23	0.95	0.94
5	—	1.09	1.26	0.95	—
60	1.07	1.11	1.44	0.94	0.89
240	—	1.11	—	0.92	—

*The effect of  $p_H$ .* Between  $p_H$  5.8 and 8.3 cells suspended for one hour in KCl (350 m.eq.) show the same increase of K—about 11%. At lower  $p_H$  values haemolysis occurs: the increase in cell K is more marked and the influence of temperature (insignificant between  $p_H$  5.8 and 8.3) becomes more obvious. At  $p_H > 8.3$ , the increase in cell K is again more marked. The observations of Mond on the increased permeation of cation at high  $p_H$  values are thus confirmed and, whilst the increase at a very high  $p_H$  may be partly due to chemical damage of the erythrocyte membrane, the increase which is still evident between  $p_H$  8 and 8.8 appears to depend mainly on physical causes. Thus cells placed first in NaCl solutions of  $p_H$  varying between 7.6 and 8.6 and then suspended in neutral KCl, show no more increase of K than cells suspended straight away in neutral KCl.

This shows that initial soaking in NaCl of moderate alkalinity does not so damage the erythrocyte membrane as to increase the permeation of K on subsequent suspension in KCl solution.

Cells placed in NaCl lose about 5 % of K except in very acid or very alkaline solutions, when the loss of K is greater.

Table IV.

Temp. ... $p_H$ (external)	KCl.			NaCl.		
	External concentration			External concentration

\* Slight haemolysis.

*Summary of changes in the cation of cells suspended in salt solutions.* The changes in cell cation observed hitherto fall into two groups. (1) Cells in salt solutions of moderate or fairly high concentration show a small rise of K in KCl solution and a small loss in NaCl. These changes are almost immediate and within wide limits are unaffected by the duration of exposure, or the reaction or the temperature of the solution used. They show only slight increases with external concentration, unless the latter is very high indeed, when the increases are much greater. (2) Cells in solutions of high  $p_H$  (8.8 or over) show a considerable change of cation and the change in cell K (whether increase in KCl or decrease in NaCl) increases with time and with rise of temperature. Similarly in neutral salt solutions of very high concentration changes in cell K with time and temperature are very evident.

It is thought that the small rapid changes of cell K observed in solutions of the first group occur in the undamaged cell, whilst the larger changes observed in the second group, which are greatly affected by the duration and temperature of suspension, indicate that cell damage has occurred.

It may be said that little can be learned from exposing erythrocytes to grossly hypotonic or hypertonic solutions; yet it has been seen that very slight changes in cell K occur when cells are placed in solutions whose concentrations vary between 100 and 350 m.eq. and that such changes are relatively unaffected by time, temperature or  $p_H$ . It therefore seems reasonable to conclude that no greater change of cell K would occur in solutions of physiological osmotic pressure. Further, the small change in K of cells exposed to solutions of such varying concentrations, indicates how strongly human erythrocytes in salt solutions resist gain or loss of their contained cation.

*The cation content of erythrocytes suspended in solutions of glucose.*

Since cell cation changes very little when erythrocytes are suspended in solutions of electrolyte, the effects of suspending cells in a solution of a non-electrolyte were investigated. It was found convenient to use a 7 % solution of

glucose, for, although its osmotic pressure is slightly higher than that of normal erythrocytes and it causes some immediate shrinkage, the subsequent diffusion of glucose into the cells increases their osmotic pressure and causes them to swell, so that after one hour's suspension in 7 % glucose cell volume is 97 % of what it was before suspension. In such a solution a considerable loss of cell K occurs and this loss is greatly increased by raising the temperature or prolonging the time of suspension.

Table V.

0.1 ml. cells in 7 ml. glucose (7%). Initial $p_H$ 6.6.						
Temp. °C.	"0" min. Glucose.		5 min. Glucose.		60 min. Glucose.	
	Final external $p_H$	$Q$	Final external $p_H$	$Q$	Final external $p_H$	$Q$
5	---	---	---	---	5.8	0.83
10	---	---	---	---	5.8	0.83
20	---	---	---	---	6.4	0.73
24	5.6	0.93	5.8	0.90	6.4	0.58
31	5.6	0.91	5.8	0.88	7.8	0.33

It will be seen that the glucose solution was slightly acid when freshly prepared, its  $p_H$  being 6.4 to 6.6. If erythrocytes are centrifuged out of such a solution after only a few moments' suspension, the supernatant glucose becomes more acid, but if the cells and fluid are left in contact for an hour, the glucose shows a marked increase of  $p_H$  (7.8-8.0). There are several possible factors concerned in these changes in reaction. Coulter [1924] remarks that this preliminary acid shift may arise from  $Cl^-$  penetrating the erythrocyte membrane more rapidly than  $K^+$  and thus escaping from the cell more rapidly, so that in fact hydrolysis of cell  $KCl$  occurs rendering the exterior more acid and the interior more alkaline. If cell K and Cl are estimated after the erythrocyte has been in glucose for 5 min. the loss of the former is 14 m.eq. and of the latter 12.5 m.eq. These differences are hardly significant from the point of view of analysis, although it must be remembered that if 0.1 ml. of cells in 7 ml. of glucose loses an amount of chloride equivalent to only 1 m.eq. per litre of cells, this amount of anion would more than suffice to change the  $p_H$  of the glucose from 6.6 to 5.6. It is probable, however, that the following mechanism is more important. When erythrocytes are suspended in a solution of  $KCl$ , a proportion of the contained  $CO_2$  and  $HCO_3^-$  diffuses outwards, the latter exchanging with external  $Cl^-$ , so that if the external solution were at first neutral and unbuffered, it now becomes slightly alkaline. But if cells are placed in a solution of non-electrolyte like glucose, cell  $CO_2$  diffuses outwards, but, as there is no external anion with which cell  $HCO_3^-$  can exchange, escape of the  $HCO_3^-$  is checked by the electrostatic attraction of the more slowly permeating cell cation. Under these circumstances, the ionisation of the  $CO_2$  diffused outwards will make the external solution more acid.

After one hour's suspension in glucose at 31°, however, practically all cell chloride, about 45 m.eq. (and presumably about 13 m.eq. of cell  $HCO_3^-$ ), has diffused outwards, while some 65 m.eq. of K have been lost, and the presence of this base-bicarbonate in the external solution renders it alkaline.

These  $p_H$  changes depending on the rapid permeation of  $CO_2$  or on the dissociated penetration of  $Cl^-$  and  $K^+$  are best seen when the time of suspension is short, but they are also evident even when the suspension time is long, provided that the temperature be low. Thus at 10°, the glucose solution remains acid even after one hour, while at higher temperatures it becomes alkaline (Table V).

*The effect of  $p_H$  on the loss of cation from cells suspended in glucose solution.*

Table VI shows that erythrocytes lose cation much more rapidly when a trace of alkali is added to the glucose in which they are suspended. This effect is more evident when the period of suspension is short. The findings further confirm Mond's observations that erythrocytes are more permeable to cation when suspended in solutions of high  $p_H$ .

Table VI.

Time min.	Erythrocytes in dextrose solution, 7° at 20°.			
	Glucose initial $p_H$ 6.6		Glucose initial $p_H$ 9.4	
	Final $p_H$	$Q$	Final $p_H$	$Q$
5	5.6	0.94	8.6	0.67
60	6.0	0.64	8.7	0.51

*Temperature coefficient of potassium loss in glucose solution* (Table V). The loss of K is small at low temperatures and the values for  $Q$  at 10° and 20° are about the same. Between 20° and 30° however K loss is greatly accelerated. Thus the reciprocal of  $Q_{20°}/Q_{10°}$  is 1.1; of  $Q_{30°}/Q_{20°}$  2.2. These figures are similar to the temperature coefficient for diffusion of phosphate into erythrocytes from phosphate solutions, which is 1.6 between 10° and 20° and 2.4 between 20° and 30° [Maizels, 1932].

*The permeability of erythrocytes in glucose to which KCl or NaCl has been added.*

The addition of quite small amounts of KCl or NaCl greatly decreases the loss of cell K. Thus the presence of only 11 m.eq. of K in the glucose solution markedly delays the diffusion outwards of cell cation, so that after one hour's suspension cell K falls from 110 m.eq. to 94 m.eq., a decrease of only 14.5%. NaCl is almost as efficient as KCl in preventing cation loss (Table VII).

Table VII.

Cells in glucose solution with and without added salts,  $T = 30°$ , time 60 min.

External glucose %	External cation species	External cation conc. m.eq.	External $p_H$	Cell volume %	$Q$
7.0	0	0	8.0	94	0.37
6.8	K	5.5	6.6	115	0.68
6.8	Na	5.5	6.6	116	0.65
6.5	K	11.0	6.6	125	0.84
6.5	Na	11.0	6.6	125	0.80
6.1	K	22.0	6.7	132	0.94
6.1	Na	22.0	6.7	135	0.88

*Changes in cell volume in glucose solutions* (Table VII). If cells are centrifuged immediately after suspension in pure glucose solution, their volume shrinks to 90% of the original volume in plasma, for the external solution is relatively hypertonic. If the suspension is allowed to stand for one hour, however, some of the glucose diffuses into the cells, carrying water with it, so that the cell volume increases to 95%. At this time cell glucose is about 3% and no doubt cell volume would be much larger than appears were there not a simultaneous outflow of cell K and Cl. If however this outflow is prevented by adding KCl or NaCl to the glucose, cell swelling resulting from the glucose diffused inwards is very evident.

## DISCUSSION.

Hitherto, the effect of external concentration on the amount of anion gained or lost by unit volume of cells has been considered; in what follows, the external concentration is compared with the concentration of ions within the cell, that is the concentration in the cell water, the cell being at equilibrium with the external solution. The latter value may be obtained as follows: if one litre of original cells after suspension in KCl solution changes to  $V$  litres containing a total of  $x$  m.eq. K, then one litre of suspended cells contains  $x/V$  m.eq. If the proportion of water in the original cell is  $a$ , then the amount of water in one litre of suspended cells is  $(V-1+a)/V$  and this water contains  $x/V$  m.eq. K. Therefore the concentration of K per kg. of cell water is  $x/V \div (V-1+a)/V$  and so  $[K] = x/(v-1+a)$ , where  $[K]$  is the concentration of cell K at equilibrium with the external solution.

In this way the concentration of the cell constituents  $[S]$  has been determined where  $S = [K] + [Cl] + [Hb]$ . Hb has been taken as 5 m.eq. Cell water was 69.5 %. Results were as follows.

External K and Cl m.eq.	$\Gamma$ $\%_0$	Internal [K] m.eq.	Internal [Cl] m.eq.	[Hb] mM	$S$
100	132	111	78	5	194
175	93	187	131	8	329
350	68.5	320	232	13	565
514	64	422	323	15	760

As the external  $p_H$  in this experiment was 7.3 it may be presumed that Hb is acting as an anion, and under these circumstances cell  $Cl^-$  should be less than external  $Cl^-$ , which is in fact the case, while cell  $K^+$  should be greater than external  $K^+$ , which is only the case with the more dilute external solutions: for when the external solution is more concentrated, cell  $[K]$  is less than external  $[K]$ . Further the sum of cell  $[K] + [Cl] + [Hb]$  should roughly equal the sum of external  $[K] + [Cl]$  or twice the concentration of external  $[K]$ . As the cell is suspended in 70 times its volume of KCl, other cell substances like bicarbonate, urea *etc.* will diffuse outwards and their concentrations both in the cell and external solution will be so low as to be negligible. If, however,  $[S]$  (fluid) and  $[S]$  (cell) are compared, it will be seen that except in the lowest concentrations  $[S]$  (cell) is much lower than  $[S]$  (fluid), and the deficiency far exceeds any possible experimental error. Further, this deficiency becomes more evident as the external concentration increases. It may be explained in one of five ways.

(1) *Presence of base in the erythrocyte in addition to potassium.* It is usually stated that human cells contain no base beside potassium, but according to recent work of Oberst [1935] they contain between 6 and 9 m.eq. Na with an average of 7 m.eq.

(2) *Presence of indiffusible compounds in the cell other than K, Na, Cl and Hb.* The osmotic pressure of such substances in the cell (complex organic phosphorus compounds, or proteins other than haemoglobin) is not likely to be significant and it is probable that compounds other than those of K, Na, Cl and Hb may be ignored.

(3) *Increased activity coefficient of the inorganic ions.* This is excluded by the work of Adair and Adair [1934].

(4) *Relatively high osmotic coefficient of the haemoglobin.* Except in very dilute solutions, haemoglobin exerts an osmotic pressure greater than would have been anticipated from its molar concentration [Adair, 1928; 1935]. This effect would be most evident with concentration of cell Hb resulting from

suspending the cell in hypertonic solutions. Adair's data apply to solutions of concentrations less than 5 mM and extrapolation is unsuited to the high concentrations found in the present experiments. However, as a rough approximation it may be said that when the concentrations of [Hb] are respectively 5, 8, 13 and 15 mM, the corresponding figures for [Hb]' in osmolar millimols are 9, 18, 34 and 46. Adding these values for [Hb] and Oberst's values for [Na] to cell [K] and [Cl] the value of  $S'$  is as follows:

$S$ external	$S'$ internal
200	205
350	350
750	605
1028	809

It will be seen that the inclusion of Na and corrected values for Hb still leaves a considerable deficiency in  $S'$  (cell), while it cannot account for the observation that cell [K] instead of being more than external [K] is less.

(5) *Part of the cell water is bound by haemoglobin and only a proportion of water is free and available as a solvent.* If such were the case, the value of  $S'$  (cell) would be correspondingly increased. According to the conclusions of Hill [1930], however, about 98% of the total erythrocyte water is free. But it is possible so to interpret Hill's data as to indicate that the ratio of free to total cell water is only 0.95 or even less. Hill estimates free water in the following manner: 1 g. of a substance (NaCl, KCl, urea, sucrose, lactic acid, succinic acid) is added to 100 g. of NaCl solution (1%) and also to a quantity of erythrocytes known to contain 100 g. of total water. The depressions of vapour pressure of each system are measured. If the ratio

Vapour pressure depression caused by adding 1 g. solute to 100 g. water in 1% NaCl solution  
 Vapour pressure depression caused by adding 1 g. of solute to 100 g. water in corpuscles (or blood)

is unity, it is concluded that all cell water is free. If the ratio is less than unity, some water is bound; if it be greater than unity, then it is assumed that the added substance "is somehow removed from free solution by the presence of other bodies, e.g. by surface adsorption, or by 'solution' in or combination with the protein or lipins". Hill's results for corpuscles and whole blood fall into three groups: lactic acid, succinic acid and urea give ratios greater than unity; the ratios for sucrose (three experiments) are 1.02, 1.02 and 0.94; for NaCl 0.99, 0.95 and 0.955; and for KCl 0.93 and 0.97. The mean of the sucrose, NaCl and KCl results are taken, indicating that less than 3% of cell water is bound, it being assumed that these three substances are not adsorbed. This is probably not the case with sucrose, and if the latter be excluded, the mean ratio for NaCl and KCl is 0.95, corresponding to 5% of bound water, or less if any adsorption of NaCl or KCl occurs. Now if succinate and lactate are adsorbed, then it is certain that chloride is also adsorbed to a significant extent. Indeed, according to Katz [1933] chloride is not less strongly adsorbed than are lactate and succinate with their hydrophile groupings, and hence it follows, from the experiments with NaCl and KCl, that bound water in the erythrocyte is greater than 5%. Hill advances another argument against the existence of bound water: "If we regard as fixed the total number of ions or molecules present in a given amount of blood, and add water to it, the depression of vapour pressure observed at any stage should be inversely proportional to the total amount of free water present at that stage. It is found that  $PV = a$  constant,  $P$  being the total osmotic pressure of all the dissolved constituents and  $V$  the volume of water in the solution. By plotting the relation between  $1/P$  and  $V$  and extrapolating it backwards to the

axis of  $V$  it is possible to determine the amount of 'free' water in the original blood". The results so obtained in these experiments showed that 7, 8 and 0% of total cell water was bound (average 5%). The advantage of this second method lies in the apparent exclusion of adsorption effects. The results can however be interpreted in another fashion. If only part of the cell water were free, then, on adding water to cells, the resulting osmotic pressure would be less than anticipated from the known cell water content; but if the addition of water resulted in the removal of substances normally adsorbed on the cell, then the osmotic pressure of the system would be raised. With the addition of more water, further de-adsorption would occur, and over a small range of dilution the findings might simulate those expected on the assumption that all cell water were free and that no de-adsorption occurs.

While the evidence against bound cell water is not conclusive there is certain evidence in its favour. Adair [1931] has shown that haemoglobin binds water: equilibration of dried haemoglobin with the vapour of saturated ammonium sulphate gives 0.2 g. of bound water per g. Hb; the distribution of chloride between haemoglobin in a collodion sac and an external solution of sodium chloride indicates 0.21 g. of bound water, while the figure obtained from determinations of crystal density is 0.18 [Adair and Adair, 1934]. Again, according to Brooks [1934] 1 g. of muscle protein binds 0.3 g. of water. 100 ml. of normal erythrocytes contain 30 g. of haemoglobin and this should bind 6 g. of water. In addition there are other substances in cells (proteins, lipins) which might also bind a proportion of water. In Table VIII the concentrations of  $[K]$ ,  $[Na]$ ,  $[Cl]$  and  $[S']$  have been calculated per kg. of free cell water, it being assumed that bound water constitutes respectively 5 and 10% of the total water, corresponding to 0, 3.5 and 7 g. of bound water per 100 ml. of cells. Cell water is 69.5%.

$S' = [K] + [Na] + [Cl] + [Hb]'$ , where  $[Hb]'$  is the roughly corrected value for  $[Hb]$ : it has not been further corrected for the slight increase in Hb concentration implied in the assumption that part of the cell water is bound.  $[Na]$  is derived from the values given by Oberst [1935].

Table VIII.

External concentration m.eq.

g. H <sub>2</sub> O/100 ml. cells		100			175			350			514

o.m. — osmolar millimols.

When discussing Hill's experiments, it was suggested that the presence of bound water was concealed by the simultaneous absorption of salt, and that Hill was really measuring the vapour pressure of a solution of unadsorbed ions and molecules in bound cell water. In the present experiments cell ions and molecules adsorbed and unadsorbed have been measured and also the total cell water. If the suggestion that adsorption concealed the presence of bound water were correct, then

$$\frac{\text{unadsorbed ions and molecules}}{\text{free cell water}} \text{ should equal } \frac{\text{total cell ions and molecules}}{\text{total cell water}},$$

and each should equal the external concentration. Reference to Table VIII, line 1, shows that the ratio of the total cell content to the total cell water ( $S'$ ) is roughly equivalent to the sum of external  $[K]$  and  $[Cl]$  in certain cases, being 205 when external  $[K]$  and  $[Cl]$  are each 100 m.eq., and being 350 when external  $[K]$  and  $[Cl]$  are each 175 m.eq. But for higher concentrations the value for  $S'$  (cell) is, as has been seen, much less than  $S$  (external).

It appears that in solutions of moderate concentration the adsorption of water and salts by Hb is approximately equal, but that with unlaked cells in more concentrated solutions water is more strongly adsorbed than salts. Further, as the apparent deficiency in  $S'$  (cell) becomes more marked with increase of external concentration it is also necessary to conclude that the amount of bound cell water increases. This is probable: with increase of the external concentration the erythrocyte shrinks and with increasing concentration of the contained haemoglobin more water will be bound. Thus Kunitz *et al.* [1933-34] have shown that 1 g. of Hb in 6.3% solution binds 0.14 g. of water, whilst in 10.45% solution 1 g. binds 0.22 g.

If then it is assumed that 6 or 7 g. of bound water per 100 ml. are present in cells suspended in concentrated solutions, then the values of  $S$  within and without the cell would be roughly equal, whilst the concentration of cell  $[K]$  is greater than the external concentration, which should be the case under the conditions of experiment.

*The rate of permeation of cations into erythrocytes.* Reference has already been made to the small and rapid changes in cation observed in cells suspended in solutions of KCl and NaCl. It has been noted that these changes are almost immediate and are stable for periods up to 4 hours; they are somewhat affected by the external concentration but only slightly by changes of temperature between 8 and 33°. These cation changes of the first group are contrasted with the cation changes found in solutions of extreme hypertonicity or of marked alkalinity, where cell cation increases with time and also with temperature. The findings in the first group also contrast with the findings in the case of cells suspended in glucose solutions; for whilst erythrocytes suspended in a solution of potassium-free electrolyte like NaCl retain most of their potassium, potassium is lost fairly rapidly when the cells are placed in a potassium-free non-electrolyte like glucose, and this loss increases with time and with rise of temperature. In short, there are certain small changes of cell cation which are stable and other larger changes which are influenced by time and temperature factors. It is suggested that whilst a part of the small increase of cell  $[K]$  in KCl solution may be due to the presence of intercellular solution, and to cell penetration, some at least is due to combination of KCl with the materials of the cell membrane or to adsorption at the cell surface, whilst the decrease in NaCl solution may be due to displacement of pre-existing potassium from the cell membrane and its replacement by Na. Davson [1934] rejects this possibility in the case of ox corpuscles, because the assumption implies a difference of osmotic pressure between cells and the fluid in which they are suspended; but if one accepts the presence of bound water, this discrepancy will disappear. The only alternative to the previous suggestion is as follows: only a small part of the erythrocyte interior is freely permeable to cations, while the greater part is impermeable except in the presence of grossly hypertonic external solutions. The simplicity of structure of the erythrocyte makes this alternative improbable.

If one assumes then that 5% of K in the normal cell is present on the surface, and a further 5% is adsorbed by cells in KCl solution, then in NaCl solution all the surface K will be replaced by Na, with an actual loss of 5% of K. Apart

however from this surface cation, no other cation will pass in or out of the cell. In non-electrolyte solutions on the other hand surface cation will be removed and not replaced by any other cation. Under these circumstances all the contained cation will gradually leak out of the cell.

It has been noted that the presence of only 11 m.eq. of K or Na in the external glucose will delay the escape of cation and will actually maintain a concentration of 94 m.eq. of K per g. of cell water for over one hour, whilst sodium is almost as effective as potassium. It is suggested that as long as the cation (whether Na or K) in or on the cell membrane is preserved, so long will cation within the cell remain more or less intact, and as the amount of a substance adsorbed from a solution decreases much less rapidly than the external concentration, a marked decrease of external salt might occur, without any significant decrease in adsorption. Alternatively, impermeability to cation might depend on the electrical charge on the cell, which is altered in pure glucose solution, but maintained if a small quantity of electrolyte be added.

In the case of other species which lose cation more readily than human cells, this surface action may be less important. Thus the erythrocytes of dog and ox lose potassium in sodium-free electrolyte solution, whilst human cells retain their cation even in solutions consisting mainly of non-electrolytes, so long as a trace of electrolyte is present.

#### SUMMARY.

1. Human erythrocytes are more resistant than the cells of other species to changes in their cation content. In NaCl solutions a slight loss of K occurs and in KCl a slight gain (5-10 %). The gain in KCl solutions increases slightly with external concentration, but is practically unaffected by temperature, moderate changes of  $p_{\text{H}}$  or by duration of exposure up to 4 hours. It is suggested that these small changes in cell cation may be due to adsorption.

2. In solutions of moderate alkalinity ( $p_{\text{H}}$  8.3-8.8) increased permeation of cation occurs, which is probably dependent on physical causes.

3. In solutions of extreme concentration (514 m.eq.), or of marked alkalinity ( $p_{\text{H}}$  9 or more) or marked acidity ( $p_{\text{H}}$  5.6 or less), increased permeation of cation occurs as a result of cell damage. These changes in cell cation increase with temperature and with duration of exposure.

4. In glucose solutions,  $\text{CO}_2$  at first diffuses out of the cell more rapidly than base-bicarbonate and renders the external solution acid. Thereafter, potassium and  $\text{HCO}_3^-$  diffuse out of the cell and the suspending fluid becomes neutral or slightly alkaline. The rate of loss of K from cells in glucose solution increases with time and temperature. If small quantities of KCl or NaCl are added to the external glucose, loss of cell K is greatly delayed and even after one hour's suspension the concentration of K in the erythrocyte will be eight times as great as the external concentration of K or Na. It is thought that the presence of small quantities of electrolyte in the external fluid delay de-adsorption or maintain the charge on the cell surface and so prevent loss of cation.

5. When cells are suspended in concentrated solutions of KCl, the internal concentration is apparently less than the external and it is necessary to assume that only 90 % of cell water is free.

My thanks are due to Mr G. S. Adair who has advised me on several points relating to the physical properties of haemoglobin.

# CCXXXII. THE MECHANISM OF THE REACTION OF SUBSTRATES WITH MOLECULAR OXYGEN. I.

By FLORA JANE OGSTON AND DAVID EZRA GREEN<sup>1</sup>.

*From the Biochemical Laboratory, Cambridge.*

*(Received July 1st, 1935.)*

*Cytochrome.* The most outstanding contribution to our knowledge of the mechanism of the reaction *in vivo* of substrates with molecular oxygen was the theory advanced by Keilin [1925; 1929; 1930] in which he maintained that oxidised cytochrome was reduced by substrates in presence of their respective dehydrogenases, and that reduced cytochrome was oxidised by molecular oxygen in presence of the indophenol oxidase. The reaction between substrate and oxygen was thus regarded as a process in two stages, one of which concerns the reduction of cytochrome and the other the oxidation of cytochrome. The experimental basis for this theory is briefly the following:

1. Bands of one or more of the cytochromes (*a*, *b*, *c*) are visible in practically all aerobic organisms and cells.

2. The alternate oxidation and reduction of cytochrome can be easily observed in living untreated cells of various organisms. For example by varying either the temperature or the oxygen tension of a yeast suspension, cytochrome can be converted at will from the reduced to the oxidised form or *vice versa*.

3. All factors which inhibit the activity of the dehydrogenase systems of the cell also delay the reduction of oxidised cytochrome.

4. The cells of yeast, muscle and other tissues contain an indophenol oxidase which catalyses the oxidation of both *p*-phenylenediamine and of cytochromes *a* and *c*. The activity of this oxidase is inhibited by very small concentrations of KCN and H<sub>2</sub>S, and by CO at high partial pressure and in the dark. The oxidation of cytochrome is inhibited or abolished by the same factors which inhibit or abolish the activity of the indophenol oxidase.

5. The oxidase-cytochrome system can be reconstructed from the oxidase of heart muscle preparations, and from cytochrome *c* extracted from baker's yeast. Neither oxidase nor cytochrome alone can oxidise cysteine to any appreciable extent. When however cytochrome and oxidase are brought together, they form a powerful catalytic system which oxidises cysteine to cystine very rapidly indeed.

6. There is a marked parallelism in nature between the distribution of cytochrome, the distribution of the oxidase and the respiratory activity of the cell.

Recently Haas [1934], by the use of an elegant spectroscopic technique, attempted to measure the quantitative rôle of cytochrome in the respiration of baker's yeast. By determining the concentration of cytochrome in the yeast suspension, and the number of times per unit interval that each molecule of cytochrome is reduced and oxidised, he was able to calculate what percentage of the total respiration proceeds through cytochrome. Calculation showed that for baker's yeast at 0°, the observed rate of reduction and oxidation of cytochrome can account for the entire respiration—within the limits of experimental error.

<sup>1</sup> Beit Memorial Research Fellow.

*Yellow pigment.* Warburg and Christian [1932, 1, 2] isolated a yellow pigment from bottom yeast with the following characteristics. It is a protein combined with a yellow prosthetic group and is capable of reversible oxidation and reduction. When a dilute solution of yellow pigment is added to the hexosemonophosphate dehydrogenase system of yeast or mammalian red blood corpuscles, a vigorous oxygen uptake ensues, whereas in the absence of added carrier, the dehydrogenase system is incapable of reacting with molecular oxygen. Thus the yellow pigment can function as an intermediary between hexosemonophosphate and oxygen in exactly the same fashion as methylene blue. That is to say the oxidised form of the pigment is reducible by the dehydrogenase system whilst the leuco-form is autoxidisable.

The researches of György *et al.* [1934], Euler and Adler [1934], Kuhn *et al.* [1934] and Euler, Adler and Schlötzer [1934] indicate that the yellow pigment or some simple derivative thereof is to be found in practically all types of animal, plant and bacterial cells. Warburg and Christian [1933, 2] determined the concentrations of yellow pigment in various bacteria and yeast. They found the yellow pigment in highest concentration in anaerobic organisms, and they concluded that the yellow pigment is concerned primarily in anaerobic processes. This conclusion was strengthened by the evidence of the "Wechselzahl" of the yellow pigment *in vivo*. Calculation showed that for the amount of yellow pigment present, a "Wechselzahl" of 4800 per minute was necessary in the case of baker's yeast, and of 19,000 per minute in the case of *B. pasteurianum* in order that all the respiration should proceed by way of the yellow pigment. Since the observed "Wechselzahl" of the yellow pigment when reduced by the hexosemonophosphate system *in vitro* is about 30, only 1/160th part of the respiration of baker's yeast, and 1/630th part of the respiration of *B. pasteurianum* can be assumed to involve the yellow pigment. That is to say the yellow pigment cannot be of any quantitative importance in these two highly respiring micro-organisms. But calculation showed that the respiration of *B. delbrückii* (normally anaerobic) in presence of hexosemonophosphate can be accounted for entirely on the basis of the known rate of oxidation and reduction of the yellow pigment present in the cells.

*Flavin.* Following Warburg and Christian's discovery of the yellow pigment Kuhn *et al.* [1933] succeeded in crystallising lactoflavin from milk and oboflavin from dried egg albumin. Both compounds were found to have the composition  $C_{17}H_{20}O_6N_4$  and to be related to the yellow pigment in much the same way as haematin to haemoglobin. Wagner-Jauregg *et al.* [1933; 1934, 1, 2, 3; 1935] investigated the power of animal cells to reduce flavin and found that tissue pulp or extracts can reduce flavin anaerobically in the presence of the following substrates—lactate, pyruvate, succinate, hexosemonophosphate, propaldehyde, glyceraldehydephosphate and citrate. However, the reduction process was rather slow compared with that of methylene blue. Analysis of the difference in the speeds of reduction of flavin by rat liver and frog muscle, both in presence of succinate, led Wagner-Jauregg *et al.* [1934, 1] to the discovery that the yellow pigment plays an important rôle in the reduction of flavin. There is apparently a deficiency of yellow pigment in frog muscle and a comparative abundance in rat liver. The ability of the yellow pigment to catalyse the reduction of flavin was well illustrated in experiments on the hexosemonophosphate system of yeast [Euler and Adler, 1934]. With all components of the system present, but without yellow pigment, the time for complete reduction of a given amount of flavin was greater than 200 min. With yellow pigment present, the same amount of flavin was reduced in 9 min. Wagner-Jauregg *et al.* further

found that the yellow pigment effect was most pronounced with the following substrates—hexosemonophosphate, hexosediphosphate, malate, lactate and citrate.

Wagner-Jauregg *et al.* [1934, 1, 2, 3] have proposed the theory "daß das gelbe Ferment<sup>1</sup> ein integrierende Bestandteil eine Reihe von Dehydrierungssystemen ist". It is difficult to understand the precise implication of this theory. We may conceive of the yellow pigment as actually combined with the dehydrogenase, and collaborating so to speak with the enzyme in activating substrates and catalysing the transfer of hydrogen, or we may imagine that the yellow pigment is only another link between the substrate and the oxidising agent, though in no wise associated with the enzyme. That is to say the dehydrogenase system reduces the yellow pigment, and the leuco-pigment formed reduces methylene blue, flavin or oxygen directly. Wagner-Jauregg further suggests that the cyanide-stable portion of respiration probably involves yellow pigment and flavin catalysis.

Adler and Euler [1934; 1935] have demonstrated that the enzymic oxidation of both alcohol and glucose either by methylene blue, lactoflavin or molecular oxygen is catalysed by the yellow pigment. These investigators assume as well that the yellow pigment forms some sort of combination with the dehydrogenase and is in the strict sense of the word a true enzyme.

*Glutathione.* Hopkins [1929] isolated crystalline glutathione from yeast, and Meldrum and Dixon [1930] studied its catalytic properties. The latter found that the autoxidation of glutathione depends on the cooperation of two factors, present in traces as impurities in the glutathione preparations: namely iron (or copper) and some substance able to form catalytically active complexes with metals. The rate of oxidation of crystalline glutathione is limited by the amount of the second factor present, and not by the iron. "Thermostable tissue preparations" can reduce oxidised glutathione although the tissue preparation inhibits the autoxidation of reduced glutathione. Certain other proteins behave like the thermostable preparations in inactivating glutathione, as does fresh washed muscle. Hopkins and Elliot [1931], in a study of the relation of glutathione to cell respiration, established the following. (1) The reduction of disulphide in mammalian liver proceeds with great velocity and is so much more rapid than the oxidation process that all the glutathione remains as —SH until the store of metabolites is almost entirely depleted. (2) The reduction process is enzymic and is presumably brought about by certain of the dehydrogenase systems. The oxidation of reduced glutathione is non-enzymic as shown by the fact that the rate of oxidation remains unchanged after the tissue has been heated to 70° for an hour. The oxidising system is sensitive to cyanide and is probably iron in combination with cysteine.

Mann [1932] found that glutathione is reduced by glucose in presence of the glucose dehydrogenase, and more recently Meldrum and Tarr [1935] found that

<sup>1</sup> The introduction into the literature of terms such as yellow enzyme and "Zwischenferment" has brought about a great deal of confusion. The reference to the yellow pigment as an enzyme is purely on the basis of its protein nature and heat-lability. To be consistent, cytochromes *a* and *b* should likewise be called enzymes. It would be far more satisfactory and less confusing to reserve the term enzyme in the case of oxidation systems for the material which activates the substrate, and to refer to substances such as yellow pigment, cytochrome *etc.*, merely as carriers. It is also regrettable that the new term "Zwischenferment" should be used to describe a dehydrogenase. Inasmuch as the term dehydrogenase has been used extensively in the last decade and has the virtue of specifying the nature of the catalysis, there is little reason for any change in nomenclature.

the hexosemonophosphate system of yeast or mammalian red blood corpuscles can reduce glutathione very rapidly indeed.

There are thus four generally distributed carriers which are presumed to be concerned in cellular respiration and it was the purpose of our experiments to determine to what extent these carriers can account for the reaction of substrates with molecular oxygen. In our opinion, the evidence for the rôle of any of these carriers was rather fragmentary and required considerable amplification.

It is noteworthy that Keilin has shown that the reduction of cytochrome *in vivo* takes place in the presence of lactate, succinate and glucose only. There are no data as to whether all the dehydrogenase systems as a class can reduce cytochrome or can utilise the cytochrome-indophenol oxidase system for the reaction with molecular oxygen. Harrison [1931] reconstructed the system glucose oxidase-cytochrome-indophenol oxidase and claimed to have found it very active catalytically, but our experiments indicate that this effect may not be real.

The theory that the yellow pigment is an integral part of the dehydrogenase complex rests entirely on the experimental fact that methylene blue or lactoflavin is reduced more rapidly by dehydrogenase systems in presence of the yellow pigment than in its absence. This fact might equally well be interpreted to show that the yellow pigment is reduced more rapidly than either methylene blue or lactoflavin, and that the leuco-pigment in consequence of its negative potential can reduce directly either of the hydrogen acceptors. Considered from this point of view, the yellow pigment functions purely as a carrier and not as an enzyme. What is perhaps the weakest point of the theories of Wagner-Jauregg and Euler is that although *in vitro* yellow pigment can catalyse the cyanide-insensitive oxidation of both hexosemonophosphate and alcohol, *in vivo* both processes are completely arrested by small concentrations of cyanide. The possibility must therefore be considered that the observed effects of yellow pigment may be artificial in the sense that the catalysis does not take place within the cell.

In the first part of this paper, the effects of glutathione, flavin, yellow pigment and cytochrome on the oxygen uptake of most of the known dehydrogenase systems are described. The second part includes miscellaneous experiments dealing with the general question of the mechanism of the utilisation of molecular oxygen by dehydrogenase systems.

#### EXPERIMENTAL.

*Manometric measurement of oxygen uptake.* The usual Barcroft technique was employed with KOH-soaked filter paper in the centre pot for the absorption of CO<sub>2</sub> [Dixon, 1934]. The experiments were performed at 37°. The substrate was usually pipetted into Keilin cups and introduced into the main body of fluid after equilibration. All experiments were always performed at least twice and in most cases more often. With oxygen uptakes more rapid than 500  $\mu$ l./hour, the rate of shaking of the manometers was increased from 120 to 175 oscillations/min.

*Preparations of enzymes.* The method of preparation is described in the appropriate section for each enzyme. In general standard methods were used, though new methods were developed for preparing the lactic, glucose, succinic, malic and  $\alpha$ -glycerophosphoric dehydrogenases. A high speed ball mill was found to offer a successful means of extracting enzymes from yeast<sup>1</sup>. We are

<sup>1</sup> The problem of extracting enzymes from micro-organisms by the method of fine grinding is now being studied *in extenso* by one of us (D. E. G.) in collaboration with V. H. Booth.

indebted to J. W. Barnard of the National Institute for Medical Research for the loan of this ingenious steel ball mill, devised by Barnard and Hewlett [1911]. Cakes of Delft or English baker's yeast were plasmolysed with sodium chloride and ground in the ball mill for 15 min. at 1500 r.p.m. The charge of yeast was usually 20–25 ml. The suspension was removed from the mill and centrifuged hard for 30 min. The viscous yellow fluid was carefully decanted and mixed with three volumes of saturated ammonium sulphate. The fine precipitate was filtered, collected on hardened paper and thoroughly dried by pressing out the moisture. The precipitate was then dissolved in about 20 ml. of phosphate buffer  $p_H$  7.2. Methylene blue experiments disclosed the presence of fairly active lactic,  $\alpha$ -glycerophosphoric, hexosemonophosphoric and hexosediphosphoric dehydrogenases as shown by Table I.

Table I.

Enzyme ml.	Methylene blue, 1/5000 ml.	Cozymase 400 units/ml. ml.	Substrate, 1 ml. of $M/10$	Time in min.
1	1	0.5	—	> 30
1	1	0.5	Lactate	1
1	1	0.5	Hexosemonophosphate	4
1	1	0.5	Hexosediphosphate	4
1	1		$\alpha$ -Glycerophosphate	7

The lactic enzyme is particularly active. In some cases 1 ml. of the buffered enzyme solution took up as much as 2000  $\mu$ l. oxygen in one hour in presence of lactate and some suitable carrier. It is also interesting to note that the extract of ground yeast contains the indophenol oxidase. The oxidase can oxidise *p*-phenylenediamine to the characteristic blue oxidation product but takes up oxygen slowly in presence of *p*-phenylenediamine.

*Coenzymes.* Cozymase was prepared by the method of Myrbäck [1933]. The purification process was carried as far as the precipitation with mercuric nitrate. The strength of the cozymase solution was determined by comparing the rate of reduction of methylene blue by the glucose dehydrogenase system in presence of graded dilutions of the unknown solutions with the rate of reduction in presence of graded dilutions of a standard cozymase solution kindly supplied to us by Dr Myrbäck. Since the activity of the glucose dehydrogenase is proportional to the concentration of cozymase within fairly wide limits, the method is capable of a high degree of accuracy.

The hexosemonophosphate cozymase was prepared from horse blood by the method of Warburg and Christian [1932, 2].

The lactic cozymase from heart was prepared by the method of Banga *et al.* [1932]. When tested with various dehydrogenase systems, it failed to yield as satisfactory results as cozymase. Probably our cozymase solutions were more concentrated than were the solutions of lactic coferment. The comparison therefore of relative activities may not be valid.

*Intermediary carriers.* Cytochrome *c* was prepared by the method of Keilin [1930]. There is a tendency for cytochrome in the form of the acid haematin to go into solution when being washed after  $SO_2$  precipitation. It was found that washing with 1% trichloroacetic acid rather than distilled water checked the tendency of precipitated cytochrome to dissolve and permitted very thorough extraction of all water-soluble impurities. The strengths of the cytochrome solutions were determined by colorimetric comparison with standard solutions of pyridine-mesohaemochromogen, the absorption spectrum of which is very similar

to that of cytochrome. Since cytochrome solutions tend to deteriorate on standing for more than a fortnight even at 0°, the bulk of the precipitated cytochrome was left suspended in 1% trichloroacetic acid and dissolved in alkali when required.

Oxidised glutathione was prepared by the method of Pirie [1931]. 400 mg. were dissolved in 25 ml. of distilled water, the free acid was neutralised with NaOH and the volume made up to 100 ml.

Solutions of purified lactoflavin were obtained from the I.G. Farbenindustrie through the courtesy of Prof. P. György. The solutions, which contained 1 mg. in 2 ml., were diluted to yield a final concentration of 100γ lactoflavin per ml. A sample of synthetic ribose-flavin in a concentration of 10γ per ml. was also used for comparison purposes.

We are indebted to Prof. O. Warburg for his generous gifts of yellow pigment in the form of the crude and the purified preparations. The former was used as a 20% solution, the latter as a 5% solution, both of which are equivalent to 15γ lactoflavin per ml.

### RESULTS.

*Succinic dehydrogenase and indophenol oxidase.* These two enzymes are invariably concomitant in extracts of animal tissues, and the following methods of preparation apply to both. Ox or sheep heart was minced, washed with 20 volumes of tap water at least 5 times and then ground with fine quartz sand in a mechanical mortar for 30 min. The resulting pulp was squeezed through muslin. The haemoglobin-rich liquid was brought to  $p_H$  4.6 with acetic acid and centrifuged for 10 min. The supernatant fluid was discarded and the colourless sediment was suspended in phosphate buffer  $p_H$  7.2. The enzyme "solution" may be kept for a week at 0° without serious loss of activity.

The enzyme "solution" prepared from ox heart contains an indophenol oxidase which is about twice as active as the succinoxidase whereas the enzyme "solution" prepared from sheep heart contains the two enzymes in approximately the same strengths (see Table IV).

A succinoxidase was also prepared from ox liver. The fresh tissue was minced in a Latapie mincer. The pulp was mixed with 3 volumes of Ringer's solution and allowed to stand 30 min. before centrifuging. The supernatant fluid was mixed with 2 volumes of saturated ammonium sulphate solution and the precipitate filtered off. The precipitate was resuspended in saturated ammonium sulphate solution and filtered until dry on a Büchner funnel. The precipitate was then dissolved in phosphate buffer  $p_H$  7.2.

The potentials of the succinic-fumaric system are about 200 mv. more positive than those of flavin, yellow pigment and glutathione. Hence cytochrome alone of all the known intermediary carriers is thermodynamically capable of reduction by the succinoxidase system [Lehmann, 1929; Borsook and Schott, 1931; Kuhn and Moruzzi, 1934; Stern, 1934; Bierich *et al.*, 1934; Green, 1933; 1934].

Tables II and III and Fig. 1 show the effects of cytochrome and methylene blue on the oxygen uptake of ox heart succinoxidase. Methylene blue produces an increase of 40 % as compared with an increase of 260 % with cytochrome. It is interesting to note that cyanide in a final concentration of  $M/600$  has very little effect on the methylene blue catalysis although completely inhibiting the cytochrome catalysis. In Table IV there is a comparison of the effects of cytochrome

oxygen uptake. The increase in velocity is proportional to the concentration of added cytochrome. It is noteworthy that although the activity of the indophenol oxidase as measured by the oxidation of *p*-phenylenediamine is very low, nevertheless a large cytochrome effect is obtained. Since the indophenol oxidase is directly concerned in the oxidation of cytochrome, the question arises how an effect of the magnitude observed with the liver preparation can be accounted for on the basis of a very feeble indophenol oxidase. The explanation lies in the fact that the activity of the indophenol oxidase as measured by the oxidation of *p*-phenylenediamine seems to depend upon the presence of cytochrome. Indeed if cytochrome is added to any indophenol oxidase preparation, there is invariably a large increase in the velocity of the oxygen uptake. Spectroscopically

it can also be shown that *p*-phenylenediamine reduces cytochrome directly. Thus it may be that *p*-phenylenediamine is not acted upon by the enzyme directly except through the intermediation of cytochrome. That is to say *p*-phenylenediamine reduces cytochrome, and reduced cytochrome is then oxidised under the influence of the indophenol oxidase.

The experiments described offer clear proof (1) that the cytochrome-indophenol oxidase system catalyses the reaction of succinic acid with molecular oxygen, and (2) that when there is little cytochrome present, as in the succinoxidase of liver, there is no oxidation of succinic acid. The large blank in the ox and sheep heart preparations is probably due to the fairly high concentrations of cytochrome *a*, *b* and *c* already present. The greater magnitude of the cytochrome effect in the case of ox heart succinoxidase is likewise probably due to the presence of less cytochrome than in the succinoxidase of sheep heart.

It has been shown by Dixon [1927] that although the oxidation of sodium succinate is inhibited by cyanide it is not inhibited by CO which inhibits the indophenol oxidase. Keilin [1929] suggested the explanation that the indophenol oxidase, being in much higher concentration than succinoxidase, is never working at maximum velocity. Consequently the partial inhibition of the oxidase by CO cannot be detected by changes in the oxygen uptake of the preparation.

*Lactic dehydrogenase.* The enzyme was prepared from fresh yeast by the method of ball mill grinding described above. The dehydrogenase in presence of lactate will reduce methylene blue without addition of cozymase. However, the addition of cozymase usually increases the speed of reduction considerably. Furthermore, in oxygen experiments there is a tendency for the activity of the enzyme to fall off rapidly with time when no coenzyme is provided. It appears therefore that the lactic enzyme of yeast is quite normal with respect to its dependence upon a coenzyme and the incomplete dependence may be due to the fact that the coenzyme is either chemically bound or adsorbed in such a way as to resist washing out.

Table VII shows the effects of various carriers on the oxygen uptake of the lactic dehydrogenase. Only methylene blue and cytochrome are at all effective

as respiratory carriers, the former producing an increase in the oxygen uptake of 430% and the latter an increase of 507%. *M*/600 cyanide has no effect whatsoever on the methylene blue catalysis but completely poisons the cytochrome catalysis. The addition of cytochrome without oxidase does increase the oxygen uptake from 68  $\mu$ l. to 149  $\mu$ l., but it must be remembered that the

extracts of ground yeast contain a certain amount of indophenol oxidase although very small in comparison with the lactic enzyme. Reducing the concentration of cytochrome to one-quarter reduces the cytochrome oxidase effect almost by one-half. Table VIII and Fig. 3 show that the cytochrome effect is sustained with time.

Fig. 3. The effect of varying cytochrome concentrations on the oxygen uptake of the yeast lactic dehydrogenase. Concentration of cytochrome  $3 \times 10^{-4} M$ . I, no cytochrome; II, 0.25 ml. cytochrome; III, 0.5 ml. cytochrome; IV, 1 ml. cytochrome.

*$\alpha$ -Glycerophosphate dehydrogenase.* The enzyme was prepared from Delft yeast by the method of grinding in the ball mill, and from the skeletal muscles of rabbit by the following method. The muscles dissected from the hind legs of a freshly killed rabbit were minced in a Latapiemincer. The pulp was washed several times with Ringer's solution, ground with quartz sand for 30 min. and suspended in  $M/4$  phosphate buffer  $p_H$  7.2. The grinding must be very efficient in order to obtain a sufficiently homogeneous suspension which can be easily pipetted. Numerous attempts were made to extract the enzyme from the tissue but none was successful. It appears that the  $\alpha$ -glycerophosphate dehydrogenase is closely associated with tissue particles and cannot be brought into solution. The enzyme is specific for the  $\alpha$ -form of glycerophosphoric acid. The product of oxidation is as yet unknown. Presumably it is glyceraldehydephosphoric acid. Both the yeast and the animal enzyme can reduce methylene blue or oxygen in presence of  $\alpha$ -glycerophosphate. No coenzyme is required. The addition of cozymase or any other coferment has no effect on the velocity of oxidation.

Tables IX, X, XI and XII contain the pertinent data for the  $\alpha$ -glycerophosphate enzymes of yeast and muscle. The small increases occasioned by methylene blue rather indicate that the enzymes are both aerobic oxidases. The

ability to react directly with oxygen can never be eliminated by any amount of washing, precipitation *etc.* *M*/600 KCN inhibits the enzyme of rabbit muscle 20 %, and the enzyme of yeast 40 %. Cytochrome, yellow pigment and flavin have, if anything, inhibitory effects on the velocity of oxygen uptake. Glutathione, in several experiments, was found to increase the oxygen uptake slightly but definitely although there was no evidence that glutathione could be reduced anaerobically by the  $\alpha$ -glycerophosphate system.

*Formic dehydrogenase.* The enzyme was prepared from *Bact. coli* by the method of Stickland [1929] and stored at 0°.

Table XIII shows the effect of intermediary carriers on the oxygen uptake. The blank of the preparation in absence of formate is rather high (50  $\mu$ l. in

45 min.) and the addition of formate hardly increases this value. Methylene blue increases the rate of formate oxidation about fifteenfold. *M*/600 KCN inhibits the methylene blue catalysis by about 50%. Flavin, glutathione and cytochrome have very small effects on the oxygen uptake. Little significance can be attached to effects of such magnitude. The effect of yellow pigment is definite though small. It should be pointed out that there is no effect of these carriers on the blank reaction, and that the effect is entirely on the oxidation of formate.

The formic enzyme solution contains the entire formic activity of the bacterial suspension used in the preparation [Stickland, 1929] as measured by methylene blue reduction. It was of interest therefore to compare the reaction with molecular oxygen of a given amount of formic enzyme with the equivalent amount of enzyme in the intact bacterial cells. Table XIV shows this comparison.

Methylene blue enables the cell-free enzyme to react with oxygen at the same speed as that in presence of the natural carrier *in vivo*. The table offers another proof that neither yellow pigment, flavin, cytochrome nor glutathione can be identical with the natural carrier for the formic enzyme in *Bact. coli*.

*Hexosemonophosphate dehydrogenase.* The enzyme was obtained from three sources: (1) horse corpuscles washed thrice with 0.9% NaCl and laked with distilled water, (2) dialysed yeast juice, and (3) the ammonium sulphate precipitate of dialysed yeast juice. Considerable difficulty was encountered in the preparation of the enzyme from maceration extract of bottom yeast by the method of Warburg and Christian [1932, 2], the final preparations being rather inactive. None of the preparations from the above three sources attained the activity recorded by Warburg and Christian. However, the activities were sufficiently high to test the action of intermediary carriers. The coferment from horse corpuscles was used in all the experiments quoted below. Euler and Adler [1934] have claimed that cozymase can replace the Warburg coferment in the hexosemonophosphate system. Our experience has been that, in aerobic experiments, the two coferments are not equivalent. A sample of cozymase (400 Co units per ml.) which enabled the glucose system to work at maximum velocity

was hardly as efficient as crude Warburg coferment in the hexosemonophosphate system.

Table XV shows the effects of methylene blue, yellow pigment, flavin, glutathione and cytochrome on the aerobic oxidation of hexosemonophosphate by the enzyme of horse corpuscles. Yellow pigment and methylene blue are extremely active, in accordance with the findings of Warburg and Christian [1932, 2], but flavin, glutathione and cytochrome are inactive.

O <sub>2</sub> uptake ( $\mu$ l./30 min.)	14	292	0	0	157	21	15

In experiments with the hexosemonophosphate enzyme from the two other sources, *viz.* dialysed yeast juice and the ammonium sulphate precipitate of yeast juice, yellow pigment was again found to be the only natural carrier with positive effect.

Meldrum and Tarr [1935] have found that the hexosemonophosphate system can reduce glutathione either aerobically or anaerobically. The inability of glutathione to act as an aerobic carrier must therefore be due to its slowness of autooxidation under the experimental conditions obtaining.

*Hexosediphosphate dehydrogenase.* It is generally assumed that the same dehydrogenase activates both hexosemonophosphate and hexosediphosphate. There are three lines of evidence in favour of this view. (1) The two enzymes always accompany one another. (2) The Warburg coferment from horse corpuscles is required by both enzymes. (3) The reactions of the two enzymes towards yellow pigment, methylene blue, KCN *etc.*, are more or less similar. While investigating the possibility of obtaining a hexosemonophosphate enzyme from sources other than yeast or red blood cells, we observed that the ratio

$$\frac{\text{activity towards hexosemonophosphate}}{\text{activity towards hexosediphosphate}}$$

varied widely. In some cases the hexosediphosphate system was far more active, in other cases the reverse was true. The question of the identity of these two enzymes requires therefore further investigation.

Enzymes can be prepared from liver, heart and other tissues which will reduce methylene blue fairly rapidly in presence of Warburg coferment and hexosediphosphate. Unfortunately the reaction of these enzymes with molecular oxygen in presence of methylene blue or yellow pigment is feeble and falls off rapidly with time. Horse corpuscles were found to offer the most satisfactory source of the enzyme.

Table XVI contains the data for the hexosediphosphate system. Yellow pigment produces the greatest increase (220 %). Methylene blue and glutathione are somewhat less effective. The flavin catalysis is small. The cytochrome control experiment shows that the cytochrome-indophenol oxidase system has no effect on the oxygen uptake.

% increase	—	158	—	—	220	73	177

*Glucose dehydrogenase.* The enzyme was prepared from liver (1) by the standard method of Harrison [1933] and (2) by our own method. Finely minced liver was dried *in vacuo*, ground to a fine powder and suspended in water for 30 min. The murky solution was centrifuged and the precipitate discarded. The supernatant fluid was dialysed for 2 days against distilled water (4 changes) and then fully saturated with ammonium sulphate. The precipitate was filtered off and dried *in vacuo*. The preparation can be kept for several months at 0° without much loss of activity. The enzyme was prepared for use by grinding this liver powder with phosphate buffer  $p_H$  7.2 and centrifuging down insoluble material.

Cozymase was used in preference to the Harrison coenzyme since it can be prepared in a comparatively pure and concentrated state.

Tables XVII, XVIII, XIX show the effects of the various carriers on the oxidation of glucose by the enzyme of dried liver. Methylene blue increases the oxygen uptake two- or three-fold and  $M/600$  KCN augments this catalysis. Flavin and cytochrome have practically no effect. Yellow pigment and glutathione both produce definite increases. Table XX shows a more pronounced yellow pigment effect with another preparation of dried liver. The magnitude of

the effect seems to be somewhat variable and dependent upon the particular preparation.

Adler and Euler [1935] have already observed the increase of the glucose oxidation by yellow pigment. Their theoretical conclusions from this observation will be discussed elsewhere.

Harrison [1931] produced evidence that the cytochrome-indophenol oxidase system catalyses the reaction of glucose with molecular oxygen in presence of the enzyme. We have been unable to confirm his results using various preparations of the glucose enzyme, of cozymase, of the glucose coenzyme, of cytochrome and of the indophenol oxidase. Tables XXI and XXII compare the actions of the cytochrome-indophenol oxidase system on the Harrison enzyme and on the dried liver preparation. If anything the cytochrome-indophenol oxidase system is inhibitory. It should be mentioned that in all experiments involving the

addition of cytochrome and the oxidase, these components had been previously tested for activity with the succinoxidase or lactic enzyme, and unless an increase in the oxygen uptake of several hundred per cent. was obtained, they were not used with other systems. There have been cases in which the addition of cytochrome and indophenol oxidase increased the oxygen uptake two- or three-fold, but in all such cases appropriate controls disclosed (1) that the effect was to a great extent independent of the presence of glucose and (2) that the total effect was the sum of the individual effects of cytochrome or oxidase.

Mann [1932] observed the anaerobic reduction of oxidised glutathione by the glucose system. The relative inefficiency of glutathione as an aerobic carrier in this system once again must be referred to the sluggish autoxidation of the reduced form under the conditions of the experiment.

#### *Aerobic oxidases.*

This class of oxidising enzymes is capable of reacting directly with molecular oxygen in the complete absence of intermediary carrier. Some of the aerobic oxidases, like xanthine oxidase, reduce methylene blue or any other suitable hydrogen acceptor; the rest, like the urico-oxidase, are specific for molecular oxygen. It was considered of interest to test the effect of natural carriers on the oxygen uptake of three representative aerobic oxidases—xanthine, urico- and amino-acid oxidases.

*Xanthine oxidase.* The enzyme was prepared from whey by the method of Dixon and Kodama [1926]. The dried powder was dissolved in phosphate buffer  $p_H$  7.2 and used directly. Table XXIII contains the data for the xanthine

oxidase system. Methylene blue increases the oxygen uptake 25 %. All the other positive effects are too small to merit any attention. Flavin in the concentration used exerts a strong inhibition. Green and Dixon [1934] have shown that the flavin present in milk cannot account for the reaction of xanthine oxidase with molecular oxygen.

*Urico-oxidase.* The enzyme was prepared from pig liver by extracting with acetone, pulverising the dried residue and suspending 1 g. in 10 ml. of borate buffer  $p_H$  8.5. The uric acid was suspended in buffer of the same  $p_H$  in a concentration of 10 mg. per ml. As the oxidation proceeds, the suspended uric acid gradually goes into solution. Table XXIV shows that none of the natural intermediary carriers has any effect.

*Amino-acid oxidase.* The enzyme was prepared from pig kidney by the method of Krebs [1935]. Table XXV shows that the oxidation of alanine is not affected appreciably by any of the natural carriers.  $M/600$  KCN has no inhibitory effect, in agreement with the findings of Krebs [1933].

*Malic dehydrogenase.* The method of preparation from ox heart is identical with that of the indophenol oxidase except that prolonged centrifuging is substituted for precipitation by acetic acid. The sediment is re-suspended in phosphate buffer  $p_H$  7.2. Szent-György's lactic coferment or cozymase is required for the activity of the malic system. The enzyme is very labile indeed and the activity falls off rapidly in presence of oxygen and the substrate. Table XXVI shows that flavin and yellow pigment both increase the oxygen

uptake by 200 and 90% respectively. This is the first case in which flavin is more efficient than yellow pigment. The magnitude of the flavin effect depends upon the concentration. When the amount of flavin added is reduced to 10 $\gamma$ , the effect becomes very small. Consideration of the control experiment with cytochrome and indophenol oxidase discloses that there is no appreciable effect on the malic oxidation.

#### *Quantitative proportions of enzymes in animal tissues and yeast.*

In evaluating the quantitative rôle which a natural carrier plays in respiration, it is not only necessary to establish which of the various oxidising systems utilise this carrier but also what proportion of the total respiration these

oxidising systems constitute. Booth, Green and Ogston, in unpublished work, have attempted to estimate quantitatively the amounts of the various dehydrogenase and oxidase systems in different tissues. They have found that the most active dehydrogenase systems in practically all tissues are the succinic, hexosemonophosphoric, hexosediphosphoric and  $\alpha$ -glycerophosphoric. The lactic and malic systems are much weaker, whilst the citric, alcohol and aldehyde systems are quantitatively negligible. There are of course certain enzymes which are very active in one particular tissue but do not have a general distribution, *e.g.* the glucose enzyme in liver, the urico-oxidase and amino-acid oxidase in liver and kidney, or the xanthine oxidase in liver.

In Part II (p. 2005), the relative strengths of different dehydrogenases in intact yeast are shown. The principal enzymes are the lactic, hexosemonophosphoric, hexosediphosphoric,  $\alpha$ -glycerophosphoric and alcohol dehydrogenases. Whether the oxidation of glucose involves a special glucose dehydrogenase or whether the glucose becomes phosphorylated prior to oxidation is uncertain. If the first alternative is correct, then the glucose enzyme is one of the most active. In yeast the succinic, malic, formic, xanthine, citric and amino-acid enzymes have very little activity and it is doubtful whether they are even present.

Thus it appears that the important cytochrome-reducing system in animal cells is the succinic, whilst in aerobic yeast the lactic takes the place of the succinic.

We have been unable thus far to obtain active citric, alcohol and glutamic dehydrogenases. However, with the exception of the alcohol system in yeast, these dehydrogenases are quantitatively unimportant. Unfortunately the malic and hexosediphosphoric enzyme systems we have worked with were not completely satisfactory from the point of view of activity. The results obtained with these two enzymes must therefore be considered with reservations. It is hoped to verify the observed effects with more potent enzyme preparations.

#### DISCUSSION.

Table XXVII summarises the results for the various dehydrogenase and oxidase systems.

The experiments with the different dehydrogenase systems disclose the extraordinary fact that of the 11 systems studied only the succinic and lactic can utilise cytochrome and indophenol oxidase for the *in vitro* reaction with molecular oxygen. How can this fact be reconciled with the general theory of Keilin?

The evidence that Keilin [1925; 1929; 1930] has adduced in favour of the view that dehydrogenases as a class react with molecular oxygen by means of cytochrome consists of the two observations, (1) that cells or tissues in anaerobiosis maintain cytochrome in the reduced state and (2) that agents like ethylurethane which inhibit the action of dehydrogenases have a similar effect on the reduction of cytochrome. When dealing with cells or tissues oxidising a variety of substrates, there is no way of deciding which particular substrate is reducing cytochrome. If, for example, yeast cells are found to reduce cytochrome in anaerobiosis, the effect may be brought about by one system, two systems or a group of systems. The spectroscopic observation of whole cells therefore can provide little information concerning the substance or substances reacting with cytochrome. Furthermore, the fact that ethyl urethane and other reagents affect dehydrogenases in the same way as they affect the *in vivo* reduction of cytochrome does not

Table XXVII.

necessarily imply that all dehydrogenases must reduce cytochrome. The observation offers proof that some dehydrogenase or group of dehydrogenases is involved but the actual number of systems cannot be deduced from the observation. When Keilin [1929] washed and aerated yeast as thoroughly as possible, he found only two substrates which increased the speed of the blank reduction of cytochrome, namely lactate and glucose. If it be assumed that glucose on oxidation gives rise to lactic acid, there is complete agreement between our results and those of Keilin. That is to say the lactic is the principal and perhaps only system in yeast utilising cytochrome and the indophenol oxidase. Spectroscopic observation of washed heart muscle showed that of a large number of substrates tried only succinic acid had any appreciable effect on the rate of reduction of cytochrome. Here again our results and those of Keilin are in agreement in designating succinic acid as the principal substrate of the cytochrome system in animal tissues.

There is the possibility that the *in vivo* reduction of cytochrome by dehydrogenase systems (the succinic and lactic excepted) is not direct but involves a chain of reactions the first of which concerns the substrate and the last cytochrome. If such were the case then it would be impossible to couple dehydrogenases *in vitro* with the cytochrome-indophenol oxidase system unless the hypothetical factors concerned in the links between cytochrome and the substrate were likewise supplied. There is however no evidence for the existence of any intermediary links.

Goszy and Szent-Györgyi [1934] have suggested that the succinic-fumaric system acts as a link between the cytochrome system and substrates in the following fashion. Succinate becomes oxidised to fumarate at the expense of the reduction of cytochrome. Fumarate then reacts with some metabolite such as lactate to yield pyruvate and succinate. In this scheme only a small amount of the succinic-fumaric system is necessary to oxidise a comparatively large amount of substrate. Furthermore, the scheme allows of the entire respiration proceeding through cytochrome without the necessity of a direct reaction between cytochrome and the substrate. Green *et al.* [1934] showed that reactions between dehydrogenase systems do not proceed unless a suitable carrier is provided. The theory of Goszy and Szent-Györgyi amounts to the statement that the succinic-fumaric system can react directly with the lactic-pyruvic system in absence of a

carrier provided that the fumaric acid is supplied in the nascent state. In the experiments of Green *et al.* the fumaric acid was added directly and did not arise by oxidation. Experiments designed to test the theory are described in Part II (p. 2005). No evidence was forthcoming that the theory is correct.

Warburg *et al.* [1933] have recently suggested that oxygen reacts with the substrate through 5 links in the following order: (1) Atmungsferment (*i.e.* indophenol oxidase), (2) some unknown haematin and (3), (4) and (5) the three components of cytochrome. One of the three components of cytochrome, let us say *c*, is reduced by the substrate; *c* in turn reduces component *b* *etc.*, until the Atmungsferment is finally reduced. Assuming the theory to be correct, the objection may be raised to our experiments that unless the three cytochromes are all present, there is no way of testing whether a particular dehydrogenase react with the cytochrome system. It is true that only cytochrome *c* is added in the *in vitro* experiments. But the indophenol oxidase which is likewise added contains definite though small amounts of *b* and *a*, the reduced bands of which are easily seen with a hand spectroscope. Thus in all experiments the three components of cytochrome are present, albeit in disproportionate amounts. Furthermore if the presence of all three components in similar concentration is required, it is difficult to explain the enormous catalyses produced by cytochrome *c* in the succinic and lactic systems.

It is interesting to calculate how many times per minute each molecule of cytochrome is reduced and oxidised by the lactic dehydrogenase-indophenol oxidase system. Under optimum conditions<sup>1</sup>, the oxygen uptake with 1 ml. of  $1 \times 10^{-4} M$  cytochrome *c* is 200  $\mu$ l. per 10 min. or 20  $\mu$ l. per min. Since a millimol of Fe is equivalent to 5600  $\mu$ l. of oxygen

$$1 \text{ ml. of } 10^{-4} M \text{ cytochrome} = \frac{5.6 \times 10^3 \times 10^{-1}}{10^3} \mu\text{l. O}_2,$$

$$\text{“Wechselzahl”} = \frac{20}{0.56} = 35.7/\text{min.}$$

Warburg [1934] calculated the number to be 4000 in the intact yeast cell or roughly 100 times as large as in the reconstructed system. This difference is hardly surprising and probably finds its explanation in the fact that the spatial configuration of intact cells cannot be duplicated *in vitro*.

The yellow pigment of bottom yeast has high catalytic activity with respect to the hexosemonophosphate, hexosediphosphate, glucose and malate dehydrogenases. Since the first two systems are quantitatively important in animal and yeast cells, the rôle of the yellow pigment in respiration should be very considerable, provided that the same catalyses occur in the cell. Part II of this series shows that the  $Q_{O_2}$  of baker's yeast in presence of hexosemonophosphate or hexosediphosphate is of the same order of magnitude as the maximum  $Q_{O_2}$  in presence of glucose or lactate. Hence if the “Wechselzahl” of the yellow pigment is too small to account for more than 0.5% of the respiration of baker's yeast, it must similarly be too small to account for the oxidation of the very substrates with which yellow pigment is presumed to deal.

A point of great importance which remains unknown is whether the yellow pigments of animal cells have similar catalytic properties to those of the bottom yeast pigment. The alternate oxidation and reduction of yellow pigment in animal cells has not yet been demonstrated. It is therefore premature to speculate about the rôle of the yellow pigment in animal cells.

Flavin is practically completely inactive with respect to all systems except

<sup>1</sup> By optimum conditions are implied excess of lactic dehydrogenase and indophenol oxidase, excess of coenzyme and pure oxygen instead of air.

the malic. The theory that the vitamin action of flavin is associated with oxidation-reduction properties receives little experimental support.

Glutathione presents an entirely different problem from that of the other natural carriers. When yellow pigment, flavin and cytochrome are inactive, it means that the reduction of these carriers is too slow. But in the case of glutathione and systems like the hexosemonophosphate, hexosediphosphate and glucose, the limiting factor is not the reduction process but rather the oxidation process. Where glutathione plays a rôle in respiration, there must be some substance or enzyme system which can catalyse the reaction of reduced glutathione with molecular oxygen. It remains for future research to ascertain the mechanism which the cell possesses for the oxidation of glutathione.

#### SUMMARY.

1. The ability of cytochrome *c*, glutathione, flavin and yellow pigment to catalyse the reaction of 11 dehydrogenase or oxidase systems with molecular oxygen has been tested.

Cytochrome *c* has catalytic activity only with the succinoxidase of animal tissues and the lactic dehydrogenase of yeast. The "Wechselzahl" of cytochrome *c* when being reduced and oxidised at maximum velocity is 35 per min.

Glutathione, although rapidly reduced by the glucose and hexosemonophosphate dehydrogenases, has little effect on the oxygen uptake. The limiting factor is the rate of autoxidation. Glutathione increases the reaction rate of the hexosediphosphate system with molecular oxygen.

Yellow pigment shows very high catalytic activity towards the glucose, hexosemonophosphate, malate and hexosediphosphate systems.

Flavin is inactive towards all systems except the malic dehydrogenase.

2. New methods for preparing the lactic, succinic,  $\alpha$ -glycerophosphoric, glucose and malic dehydrogenases are described. The utility of a steel ball mill for the extraction of enzymes from yeast is shown.

One of us (F. J. O.) is indebted to the Department of Scientific and Industrial Research for a grant.

# CCXXXIII. THE MECHANISM OF THE REACTION OF SUBSTRATES WITH MOLECULAR OXYGEN. II.

By FLORA JANE OGSTON AND DAVID EZRA GREEN<sup>1</sup>.

*From the Biochemical Laboratory, Cambridge.*

*(Received July 1st, 1935.)*

## I. THE EFFECT OF CYANIDE ON OXIDATIONS BY BAKER'S YEAST.

THERE is an extensive literature dealing with the effect of cyanide on the total respiration of various cells. Scanty information is available, however, on the effect of cyanide on the oxidation of known substrates by intact cells.

If a particular oxidation *in vivo* is not cyanide-sensitive, it is reasonable to conclude that this oxidation is not catalysed by cytochrome and the indophenol oxidase. On the other hand a positive cyanide effect can mean either that the cytochrome system or that some other cyanide-sensitive system is involved. That is to say cyanide inhibition is not a specific indicator of cytochrome catalysis. Complete proof of the working of the cytochrome system requires the demonstration not only of inhibition by cyanide but also of inhibition by  $H_2S$ , CO and  $NaN_3$ , and of the reversal of CO inhibition by light of a definite wave-length. With the exception of Warburg's [1927] study of the oxidation of alcohol, glucose and acetic acid by baker's yeast, there has been no thorough analysis of the effects of various inhibitors on the oxidations of particular substrates.

*Experimental.* In order to reduce the residual respiration to a minimum, Delft yeast was washed twice with 15 volumes of tap water, suspended in  $M/5$  phosphate buffer  $p_H$  7.2 and aerated vigorously for 6 hours. The yeast was

centrifuged and resuspended in fresh phosphate buffer. Tables I and II show the effects of cyanide on the oxidations of lactate, hexosemonophosphate, hexosediphosphate,  $\alpha$ -glycerophosphate, glucose and alcohol.  $M/600$  cyanide was used since trial experiments showed that this concentration was not high enough for toxic action and not low enough for submaximum inhibition. The results show almost complete inhibition of all the systems studied except the  $\alpha$ -glycerophosphate which was inhibited to the extent of only 64 % in this experiment. The percentage inhibition is calculated from the following formula:

% inhibition =

$$100 - \frac{\text{oxygen uptake of substrate in cyanide} - \text{oxygen uptake of blank in cyanide}}{\text{oxygen uptake of substrate} - \text{oxygen uptake of blank}}.$$

There is a certain amount of variability in the magnitude of the cyanide inhibition, but experiment has shown that there is a rule governing this variability. If for some reason (as yet unknown) a particular dehydrogenase is not active in a given sample of yeast, the small increase over the blank uptake is either very slightly or not at all affected by addition of cyanide. When, however, the enzyme is found active in other samples of yeast, the large increase over the blank reaction is largely eliminated by addition of cyanide. No oxidation has yet been found which under proper conditions was not largely inhibited by  $M/600$  cyanide.

The effect of cyanide on the oxidations of yeast suspended in  $M/5$   $\text{KH}_2\text{PO}_4$  was tried and the results were found to be similar to those in Table I.

The oxidations of hypoxanthine, succinate, formate, acetaldehyde and malate by Delft yeast were found to be insufficiently rapid to permit accurate measurement of the effect of cyanide.

The cyanide inhibitions observed raise the following questions. If the oxidation of hexosemonophosphate or hexosediphosphate involves yellow pigment catalysis, why is the catalysis cyanide-sensitive *in vivo* when there is no effect of cyanide on the isolated dehydrogenase system? If the cyanide-sensitivity *in vivo* is taken to mean the operation of a cytochrome catalysis, why cannot the hexosephosphate dehydrogenase systems couple *in vitro* with cytochrome and the indophenol oxidase? Warburg [1928], in referring to the question of the number of "Atmungsfermente", makes a distinction between experiments on isolated systems and on living cells, and states that effects which obtain with the one do not necessarily obtain with the other. This may be the answer to the dilemma arising from the cyanide experiments, though it is by no means certain.

All the evidence points to the alcohol dehydrogenase of baker's yeast reacting with molecular oxygen by way of cytochrome and the "Atmungsferment" [Warburg, 1927]. The oxidation is sensitive both to CO and cyanide. Further, the partition constant for the oxidation of alcohol in presence of different mixtures of CO and  $\text{O}_2$  is identical within the limits of experimental error with that of the "Atmungsferment". Adler and Euler [1934] have demonstrated that the alcohol dehydrogenase *in vitro* can react with molecular oxygen through the intermediation of yellow pigment, and they have concluded that the dehydrogenase normally functions in association with "Flavinenzym". It appears, however, that this catalysis may be artificial and may not take place in the living cell.

## II. THE METABOLISM OF BOTTOM YEAST.

This organism offers excellent material for testing some aspects of the theories of cellular respiration. It is normally anaerobic and contains a relatively large quantity of yellow pigment (20 mg. photoderivative/kg. dry weight,

Warburg and Christian, [1933]), but no cytochrome or indophenol oxidase. According to Windisch [1932] the  $Q_{O_2}$  of bottom yeast varies from 1 to 4 whilst the  $Q_{CO_2}^N$  lies between the limits of 80 and 120.

The question arose whether the low  $Q_{CO_2}$  of bottom yeast is due to a deficiency in some important component of the aerobic mechanism rather than to the complete absence of respiratory systems. The following experiments were carried out with a view to elucidating the causes of the low  $Q_{O_2}$  of bottom yeast.

#### EXPERIMENTAL.

Bottom yeast was obtained from (1) a Belgian brewery and (2) Barclay, Perkins and Co. Ltd., London. The yeast was washed by decantation at least 5 times with 20 volumes of tap water, and finally suspended in  $M/4$  phosphate buffer at  $p_H$  7.2.

Tables III–VIII summarise the experiments dealing with the metabolism of the English and Belgian samples of bottom yeast. The most active dehydrogenase systems are the hexosemonophosphate, hexosediphosphate, lactate, glucose and pyruvate. The effects of addition of Warburg coferment and pyocyanine show clearly that the missing components of the respiratory complement are (1) coenzyme and (2) intermediary carrier. By supplying the deficient elements, the oxygen uptake can be increased as much as tenfold. Pyocyanine is far more efficient as a carrier than methylene blue. Flavin has either no effect or a slight inhibitory effect. It is noteworthy that cozymase is not equivalent to Warburg coferment in increasing the velocity of the oxidation of hexosemonophosphate. This observation agrees with our experience of the unequal effects of cozymase and of Warburg coferment on the isolated dehydrogenase system.

O <sub>2</sub> uptake ( $\mu$ l./30 min.)	18.0	286	198

The enormous increase in respiration occasioned by pyocyanine is difficult to reconcile with the presence of relatively large amounts of yellow pigment in bottom yeast. The probable explanation is that yellow pigment is normally not concerned in the oxidations of hexosemonophosphate, hexosediphosphate and glucose. Probably the pigment is not accessible *in vivo* to these three dehydrogenase systems. Green *et al.* [1934] showed that yellow pigment was about three-fold as efficient as pyocyanine in catalysing the oxidation of hexosemonophosphate by the dehydrogenase system isolated from bottom yeast. Yet *in vivo* the oxidation of hexosemonophosphate in absence of added carrier proceeds at a negligible velocity. If the oxidation in the intact cell involved the yellow pigment, the addition of pyocyanine should have had little effect.

*M*/600 cyanide inhibits the pyocyanine catalysis of the oxidation of hexosemonophosphate by 31 %. *In vitro* *M*/200 cyanide increases the velocity of oxygen uptake of the hexosemonophosphate enzyme system by 36 % [Euler and Adler, 1934]. It appears therefore that enzymes in the intact cell are more cyanide-sensitive than in cell-free solution and that this cyanide-sensitivity in some cases may have nothing to do with haematin catalysis.

### III. COUPLING OF DEHYDROGENASES WITH THE SUCCINOXIDASE-CYTOCHROME-INDOPHENOL OXIDASE SYSTEM.

In Part I of this series, the theory of Goszy and Szent-Györgyi [1934], attributing catalytic properties to the succinic-fumaric system, was discussed in detail. Experiments are now presented showing that *in vitro* the succinic-fumaric

system cannot act as an intermediary link between cytochrome and dehydrogenases. The method of testing was simply to compare the oxygen uptake of a solution containing dehydrogenase, substrate, indophenol oxidase and cytochrome with and without the addition of succinate equivalent to  $22\mu\text{l. O}_2$ . If the succinate is constantly regenerated according to the theory, then the increase in the oxygen uptake should be many times that for the complete oxidation of the added succinate. Table IX shows that the differences in oxygen uptake

with and without succinate in the cases of the  $\alpha$ -glycerophosphate, formate, glucose and hexosemonophosphate dehydrogenases are never more than  $24\mu\text{l. O}_2$ . In other words, the reactions between activated fumaric acid and the four substrates tried cannot take place directly. The possibility remains that in the cell some carrier links fumarate and the substrate. The experiments of Green *et al.* [1934] have shown that none of the known natural carriers can function in carrier-linked reactions between dehydrogenase systems. But there may be as yet unknown carriers which perform the coupling in the cell.

#### IV. INDOPHENOL OXIDASE ACTIVITY AND THE $Q_{\text{O}_2}$ OF RAT TISSUES.

If the cytochrome-indophenol oxidase system is the principal respiratory system of animal tissues, there should exist a proportionality between the intensity of respiration and the amount of indophenol oxidase. Keilin [1925; 1929; 1930] maintained that qualitatively this relation does hold. The following experiment was carried out to test the proportionality quantitatively. Fresh tissues were weighed, thoroughly minced, washed twice with 0.9 % NaCl and ground to a homogeneous suspension in a known volume of  $M/5$  phosphate buffer  $p_{\text{H}} 7.2$ . The  $Q_{\text{indophenol oxidase}}$  was calculated on the basis of the original dry weight of the tissue prior to washing with salt solution. Trial experiments showed that no oxidase was washed out from the tissue by the salt solution. Table X contains the comparison of the  $Q_{\text{O}_2}$  and the  $Q_{\text{indophenol oxidase}}$ . Brain with the lowest  $Q_{\text{O}_2}$  of the four tissues studied has the highest  $Q_{\text{indophenol oxidase}}$ . The other three tissues have comparable  $Q_{\text{O}_2}$  and  $Q_{\text{indophenol oxidase}}$  values. It is noteworthy that the  $Q_{\text{O}_2}$  and the  $Q_{\text{indophenol oxidase}}$  are of the same order of magnitude. In other words there is approximately sufficient indophenol oxidase to account for the greater part of respiration. The agreement is not perfect but it is worth mentioning that the indophenol oxidase activity was measured in cell-free suspension whereas the  $Q_{\text{O}_2}$  was measured with the intact slice. In general there is a falling off in the activity of oxidation enzymes with extraction from the cell.

Table X. *Comparison of indophenol oxidase activity and  $Q_{O_2}$  of rat tissues.*

Brain	33.5	14	0.4

\* The figures for the  $Q_{O_2}$  were kindly given to us by Dr H. A. Krebs from unpublished work, and represent the maximum respiration of the various tissues.

#### V. THE ASSOCIATION OF THE INDOPHENOL OXIDASE WITH DISCRETE PARTICLES.

Numerous attempts were made to purify and concentrate the indophenol oxidase from heart muscle but no success was attained. Experiment showed that the heart muscle preparation represents a suspension of fine particles with which the enzyme is intimately associated. No means has yet been found of separating the enzyme from the particles. Tables XI and XII show the effect of

high-speed centrifuging on the activity of the indophenol oxidase preparation. It is clear that centrifuging, if continued long enough, will remove all the activity of both the succinic and indophenol oxidases.

#### VI. IS THE YELLOW PIGMENT A CARRIER OR AN ENZYME?

The theory of Wagner-Jauregg *et al.* [1934; Wagner-Jauregg, 1935] and of Adler and Euler [1934; 1935] that the yellow pigment works in conjunction with the dehydrogenase in reducing flavin, methylene blue or oxygen can be tested as follows. If the yellow pigment functions enzymically, then supplying flavin to the flavin-enzyme system should increase the oxygen uptake, whereas if the yellow pigment functions purely as an intermediary carrier between the substrate and oxygen, the addition of flavin should have no effect since adding flavin is equivalent to adding an oxidising agent which competes with oxygen for reduced yellow pigment. Tables XIII–XVI show that in no case does addition of lactoflavin increase the yellow pigment catalysis, and that in most cases

flavin has a definite inhibitory effect. There is therefore no basis for ascribing enzymic properties to the yellow pigment.

We are grateful to Priv. Doz. Dr Wagner-Jauregg for a sample of pure crystalline lactoflavin. No difference was found between the behaviour of our crude and his pure material.

#### SUMMARY.

1. M/600 cyanide inhibits almost completely the oxidations of lactate, hexosemonophosphate, hexosediphosphate,  $\alpha$ -glycerophosphate, glucose and alcohol by actively respiring baker's yeast. When any of these dehydrogenase systems are relatively weak in a given sample of yeast, as shown by the fact that the addition of substrate increases only slightly the blank oxygen uptake, M/600 cyanide is found to have little effect.

2. The oxygen uptake of bottom yeast in presence of hexosemonophosphate, hexosediphosphate, glucose, lactate and pyruvate is greatly increased by addition

of pyocyanine. Warburg coferment from horse corpuscles augments the pyocyanine effect in the cases of the oxidation of hexosemonophosphate and hexosediphosphate.

3. The  $\alpha$ -glycerophosphate, formate, glucose and hexosemonophosphate dehydrogenases cannot react with cytochrome through the intermediation of the succinic-fumaric system.

4. The  $Q_{O_2}/Q_{\text{indophenol oxidase}}$  ratio of rat liver, heart and kidney is fairly constant (1.5–1.9). However, rat brain has the lowest  $Q_{O_2}$  and the highest  $Q_{\text{indophenol oxidase}}$  of the four tissues studied. The  $Q_{\text{indophenol oxidase}}$  values are sufficiently high to account for the bulk of the respiration of these tissues.

5. The indophenol oxidase is associated with macroscopic particles which can be sedimented by centrifuging at high speed.

6. Flavin either inhibits or has no effect on the yellow pigment catalysis of the enzymic oxidation of glucose, hexosemonophosphate, hexosediphosphate and malate.

One of us (F. J. O.) is indebted to the Department of Scientific and Industrial Research for a grant.

# CCXXXIV. OBSERVATIONS ON THE ESTIMATION OF ASCORBIC ACID BY TITRATION.

By EARLE WILLARD MCHENRY AND MURRAY GRAHAM.

*From the School of Hygiene and Connaught Laboratories,  
University of Toronto.*

*(Received June 28th, 1935.)*

THE work of Tillmans *et al.* [1932], of Harris and Ray [1933] and of others on the estimation of vitamin C by titration against phenolindophenol has offered an opportunity to investigate quickly the antiscorbutic activity of foodstuffs. Since no information in this respect was available regarding Canadian foods, it seemed advisable to make a series of measurements. It was soon found that several modifications in the available procedures could be made to render the estimation more convenient and more accurate. We have employed the procedure of Harris and Ray [1933] with the following modifications.

(a) The indicator, 2:6-dichlorophenolindophenol, was made up in a phosphate buffer solution,  $p_H$  7.2. In this solution the indicator was found to be fairly stable, but daily standardisation is essential.

(b) The indicator was standardised against ferrous ammonium sulphate according to the method of Tillmans, Hirsch and Hirsch [1932]. Since both ferrous ammonium sulphate and ascorbic acid reduce the indophenol indicator, it was possible, through the medium of the indicator, to standardise the sulphate solution against pure ascorbic acid crystals. The slightly acidified solution of ferrous ammonium sulphate when kept under an atmosphere of nitrogen in an automatic burette showed no deterioration in 6 months.

(c) As was first noted by Zilva [1927], acid alone slowly decolorises the indophenol indicator. When titrating extracts rich in ascorbic acid the percentage error caused by the presence of trichloroacetic acid is negligible but in solutions with a low ascorbic acid content the percentage error is considerable. The time required for a given amount of trichloroacetic acid to decolorise a fixed amount of indophenol solution is considerably increased when the indophenol solution is diluted with 15-20 vols. of water. On the other hand, the same dilution only slightly prolongs the time required for the reduction of the indophenol by ascorbic acid. Consequently in this work 1.0 ml. of the indophenol indicator solution was diluted with 15-20 ml. of distilled water just prior to titration with the acidified ascorbic acid extract.

(d) When working with solid foods Birch *et al.* [1933] made only one trichloroacetic acid extraction. One extraction yields only about 60% of the free ascorbic acid contained in the tissue and it is essential to make three extractions in order to obtain an estimate of the total amount of free ascorbic acid.

(e) A final concentration of 5% trichloroacetic acid was found to have a destructive effect on various ascorbic acid extracts. A 3% solution was found to serve equally well for extraction and considerably lessened the destructive action.

(f) The addition of a few drops of potassium cyanide solution during extraction was found to have a stabilising effect on the ascorbic acid present.

(g) The use of larger volumes than those recommended by Birch *et al.* increases the accuracy of the procedure. In this work tissues were extracted as follows. To 72 g. of the solid material were added 48 ml. distilled water, 12 ml. 20% trichloroacetic acid solution and 1 ml. 0.2M potassium cyanide solution. The mixture was then ground with sand and centrifuged. The residue was twice extracted in the centrifuge cups with 40 ml. of 3% trichloroacetic acid solution to which a little potassium cyanide solution had been added. The combined supernatant fluids were then well mixed, the volume measured and the required amount filtered. The filtrate was titrated from a 5 ml. burette into a measured volume of the indicator solution.

*Titration of pigmented extracts.*

Several methods of removing the interfering pigment from cherry, raspberry, beet and other extracts were tried, but it was found that in each case in which the colour was removed a part of the ascorbic acid was also removed or destroyed. The mercuric acetate method described by Emmerie and Van Eekelen [1934] proved unsatisfactory in this laboratory, since only about 70 % of added ascorbic acid could be recovered.

In one experiment using the mercuric acetate procedure the following results were obtained. 50 ml. of untreated turnip juice containing 6.8 mg. ascorbic acid were mixed with 5 ml. of an ascorbic acid solution (B.D.H. tablets) containing 13.8 mg. ascorbic acid. 55 ml. of this mixture and 50 ml. of the same turnip juice but without added ascorbic acid were then treated with mercuric acetate as described by the above authors. On titrating the final solutions it was found that the turnip juice alone contained 3.8 mg. and the turnip juice *plus* the ascorbic acid solution contained 13.7 mg. Assuming, as is reasonable, that the 50 ml. of turnip juice in the mixture accounted for 3.8 mg., then only 9.9 mg. or 72 %, of the added ascorbic acid could be determined.

It was thought that ascorbic acid might have been carried down with the precipitate which is formed. To test this, a solution of pure ascorbic acid was treated with mercuric acetate as before. Again only 70 %, of the ascorbic acid originally present could be determined. A control solution treated as above except for the addition of mercuric acetate showed practically no change. The fact that ascorbic acid when in the reversibly oxidised state is known to be quite unstable tends to explain the above results and it is likely that ascorbic acid, partially oxidised by the mercuric acetate, is very quickly irreversibly oxidised.

A modification of the method described by Tillmans, Hirsch and Jackisch [1932, 1] for titrating pigmented extracts was finally adopted. The basis of this procedure lies in the fact that most plant pigments are insoluble in chloroform whereas the indophenol indicator is more soluble in chloroform than in water and may be completely removed from aqueous solution with this solvent. About 10 ml. chloroform are placed in a 50 ml. centrifuge-tube. Then 5, 10 or 20 ml. tissue extract, depending on its probable ascorbic acid potency, are added. A pipette connected to a cylinder of carbon dioxide is then lowered into the aqueous layer so that, on bubbling the gas through, the aqueous layer is thoroughly mixed but the chloroform layer is not disturbed. While the aqueous layer is being thus stirred, the indicator solution is added drop by drop from a 5 ml. micro-burette. An approximate preliminary titration is carried out to estimate the amount of indicator required. After the addition of the estimated amount of indicator it is advisable to wait a short time to allow for the complete reaction of the indicator and any ascorbic acid present. Then the tip of the pipette is lowered into the chloroform and carbon dioxide bubbled in for about a minute at a rate sufficient thoroughly to mix the two layers. The two layers are then separated by centrifuging. If the chloroform is practically colourless, insufficient indicator has been added and the titration must be continued. The end-point is reached when just sufficient indicator has been added to give the chloroform a definite red tinge. With practice the titration can be carried out fairly quickly. The red colour in the chloroform is quite stable and does not fade as is the case in acidified aqueous solutions. Using this method it has been found possible to account for 97-99 % of added ascorbic acid.

The pigments of strawberries and red peppers were found to be somewhat soluble in chloroform and for these the above method could not be employed. However, these pigments, in contrast to those of raspberries, cherries *etc.*, may be sufficiently removed to permit ordinary titration by shaking up the tri-

chloroacetic acid extract with butyl or amyl alcohol. If the alcohol is subsequently washed with a small volume of water and the water added to the original extract, the loss of ascorbic acid is not significant.

*Rapid destruction of ascorbic acid in minced vegetables.*

When shredded turnip is allowed to stand in the open air for a short time, the juice obtained by pressing the pulp is inactive or practically so as far as reducing the indophenol indicator is concerned. This result has also been noted by Ahmad [1935]. If the juice is pressed out immediately after shredding, the activity is retained in the juice fairly well. However, juice expressed from pulp which had been standing about 10 minutes did not retain what little activity it possessed but became inactivated quite rapidly. The inactivation of the pulp is practically complete in 30 minutes and even in 15 minutes the pulp loses about 75 % of its activity.

A quantity of pulp, immediately after shredding, was suspended in acidulated water to which a little potassium cyanide had been added. The mixture was allowed to stand an hour. The liquid obtained on pressing out the mixture was found to be fairly active. When potassium cyanide alone was added to the water the inactivation of the pulp was complete in less than 45 minutes. However, when acid alone was added so that the  $p_{\text{H}}$  of the mixture was about 2.5 the juice obtained possessed considerable reducing activity. When the aqueous mixture is saturated with hydrogen sulphide practically no inactivation occurs within 24 hours. Parsnip and cauliflower pulp behaved similarly.

It appears therefore that vegetable pulp has no mechanism for stabilising ascorbic acid. On the other hand, animal tissues were found by Mawson [1935] to possess a marked ability to inhibit the aerobic oxidation of ascorbic acid.

*Ascorbic acid content of inner and outer parts of plant tissues.*

If there were a relation between ascorbic acid synthesis and photosynthesis in plants, one would expect to find the vitamin more concentrated in those parts of the plant in which photosynthesis is most active. This has been shown to be the case by Bacharach *et al.* [1934], who found that 15 % of the total ascorbic acid content of lemons was in the juice and 85 % in the peel.

This relation has also been demonstrated in the present work. Two samples were taken from the top of a firm head of lettuce and two from the bottom near the root of the same head. The four samples were then extracted and the solutions titrated. The top samples contained 5.6 and 6.2 mg./100 ml. ascorbic acid while the lower ones contained only 3.7 and 4.1 mg./100 ml. One would naturally suppose that the lower part would receive less sunlight than the upper and that consequently photosynthesis would be less active in the lower section.

In the case of cucumbers it was found that whereas the inner edible portion contained 1.5 mg./100 g. ascorbic acid, the outer skin contained 4.3 mg./100 g. or almost three times as much weight for weight.

At first it appeared that the above relationship was reversed in the case of turnips. Juice squeezed from the outer parts of two turnips was found to contain 37 and 47 mg./100 ml. ascorbic acid. Juice from the inner parts of the same two turnips contained 50 and 52 mg./100 ml. respectively. However, since practically all the photosynthesis occurs in the leaves of the turnip and since substances formed in the leaves are transferred down the stalks to the central part of the turnip, the observations in this case are in agreement with the former examples as far as the relationship between ascorbic acid production and photosynthesis is concerned.

*Polyploidy and ascorbic acid.*

Zilva [1933] reported that the juice obtained by thoroughly macerating tetraploid tomatoes was almost twice as potent with respect to vitamin C as was the juice so obtained from diploid tomatoes. He observed that the former fruits were smaller than the latter but stated that he did not think the variation in potency was a result of this difference in size.

Through the kindness of Dr MacArthur of the University of Toronto it was possible to investigate the ascorbic acid content of these two types of fruit both obtained from the same variety of tomato. The fruits were so selected that all were approximately the same size, about  $\frac{3}{4}$  in. in diameter, and appeared to be of the same degree of ripeness. It was found that, considering the weight of the whole tomato, the tetraploids contained 43 mg./100 g. ascorbic acid and the diploids contained 36 mg./100 g. The difference in the two types observed here is not nearly so marked as that observed by Zilva.

It seems possible that at least part of the difference noted by Zilva may have resulted from the difference in size of the tetraploid and diploid tomatoes which he used. Because of this difference in size it is obvious that weight for weight the tetraploids (being smaller) would have a greater surface area than the diploids and as has been pointed out above ascorbic acid is much more concentrated in the surface of such fruits than in the inner section.

The relationship between the ascorbic acid content and the size of tomatoes was illustrated in the fruit obtained from one of the parents of the diploid and tetraploid plants. These tomatoes were extremely small, being only  $\frac{3}{8}$  in. in diameter. They contained 68 mg./100 g. ascorbic acid, much more than either of the former and larger samples.

*Reduced and reversibly oxidised ascorbic acid.*

Tillmans, Hirsch and Jackisch [1932, 2] observed that the titration value of cucumber extracts was considerably increased when the extract was kept under an atmosphere of hydrogen sulphide for several hours. Before titration the hydrogen sulphide was removed by a stream of inert gas such as nitrogen. It appears that in the original extract a part of the ascorbic acid was present in a reversibly oxidised state. In the present work it has been shown that the above result is not confined to cucumber extract but is true for various plant extracts. Table I gives the amounts in mg./100 ml. of reduced and reduced *plus*

Table I. *Reduced and reversibly oxidised ascorbic acid in various tissues.*

mg. ascorbic acid per 100 g. tissue.					
Tissue	Reduced	Reduced <i>plus</i> reversibly oxidised	Tissue	Reduced	Reduced <i>plus</i> reversibly oxidised
String beans	1.4	4.0	Cabbage	15	22
Lettuce	0.30	3.8	Spinach	18	22
Cucumbers	0.80	2.0	Tomatoes	15	15
Onions	5.9	13	Lemon juice	52	52
Broccoli	32	68	Peppers (hot)	167	160
Carrots	1.2	2.1	Bovine adrenal glands	125	121
Parsnips	3.7	5.0			

reversibly oxidised ascorbic acid present in extracts of various tissues. The procedure employed in obtaining these results was to dilute the extract with an equal volume of distilled water so that the concentration of trichloroacetic

acid was about 1.5%. Hydrogen sulphide was then bubbled in for 5–10 minutes. The extract was corked tightly and allowed to stand overnight. Hydrogen sulphide was then removed by a stream of carbon dioxide; this required about 2 hours. In order to be certain that all the vitamin C present in an extract is determined by the indophenol titration method it is obvious that a preliminary treatment with hydrogen sulphide is essential.

*Effect on titration value when certain vegetables are cooked.*

During an investigation of the ascorbic acid content of a number of raw and cooked Canadian foods it was found that in the case of certain vegetables, such as cauliflower, carrots, parsnips, beets and potatoes, the titration value was higher for the cooked food than for the raw [McHenry and Graham, 1934]. A similar result in the case of cabbage has recently been reported by Bezssonoff [1934] and by Ahmad [1935]. However, in this laboratory only a decrease in the titration value of cabbage was observed after cooking. This increase when certain vegetables are cooked was reported by Tillmans, Hirsch and Jackisch [1932, 2] but seems to have escaped general notice. The following table gives the amounts of reduced ascorbic acid in extracts of raw and cooked tissues. The values are calculated in mg./100 g. of ascorbic acid. The plant tissues were heated by procedures similar to those used in preparing them for table use.

Table II. *Effect of heating upon titration value.*

mg. ascorbic acid per 100 g. tissue.

Parsnips	3.7	6.1	Turnip	35	18
Spinach	18	13	Bovine adrenal glands	125	141

In the case of cauliflower, parsnips and lemon juice, determinations have been made at regular intervals during the course of heating in order to study the rate of increase in titration value. The minced pulp of cauliflower and parsnips was suspended in a lightly acidified water to which a little potassium cyanide solution had been added. In order further to inhibit oxidation the heating was done under an atmosphere of hydrogen sulphide. After extraction the solutions were treated with hydrogen sulphide and with carbon dioxide as previously described. The results are shown graphically in Fig. 1. With cauliflower and parsnips the titration value increased rapidly at first and then gradually decreased. There was no increase on heating lemon juice but only a gradual decrease.

It was found possible to bring about this same increase in titration value, without heating, by allowing the pulp mixture to stand several hours under an atmosphere of hydrogen sulphide in 1% hydrochloric acid solution.

It is unlikely that this increase is due to cellular disintegration as a result of heating and consequently more thorough extraction of ascorbic acid. At first it seemed possible that the results might be attributed to the liberation of some sulphhydryl compound. However, colorimetric tests for cystine, cysteine and ergothioneine are practically negative in extracts of the cooked material. The most likely explanation seems to be that a part of the ascorbic acid in the tissue is bound to some other substance and that this combination is split by hydrolysis.

Combined ascorbic acid is capable of reducing the indophenol indicator but is insoluble in trichloroacetic acid solution and for this reason is not determined unless soluble ascorbic acid is first set free. The combined form is, however, soluble in water as the following experiment shows. Cauliflower pulp was well mixed and divided into six 30 g. lots. Three lots were extracted with distilled water. The other three lots were first heated and then extracted with the usual

Fig. 1. Change in titration values when cauliflower, parsnip and diluted lemon juice are heated at 58° under hydrogen sulphide.

amount of acid. Part of the extracts were then treated with hydrogen sulphide and carbon dioxide as previously described. The three heated, acid-extracted samples contained 39, 41 and 43 mg. per 100 ml. ascorbic acid. The three unheated, water-extracted samples contained 40, 39 and 41 mg./100 ml. Thus even without a preliminary hydrolysis the ascorbic acid compound is extracted with water and may be determined by titration. However, aqueous extracts are turbid, difficult to clarify and inconvenient for titration.

In another experiment an aqueous extract of cauliflower was divided into two portions. To the first was added sufficient trichloroacetic acid to give a concentration of 3% acid. The precipitate was removed by filtration. To the second portion was added a volume of water equal to that of acid added above. Both solutions were then treated with hydrogen sulphide and carbon dioxide. Calculated on the weight of cauliflower the second solution contained 50 mg./100 g. ascorbic acid and the first only 41 mg./100 g. Evidently the addition of the acid caused the combined form of ascorbic acid to precipitate.

From the above results it is apparent that a simple acid extraction and titration procedure does not give the complete value for ascorbic acid but only measures the free acid. In many plant tissues this amount is supplemented by hydrolysis. There may be present, also, an amount of reversibly oxidised ascorbic acid which is not measured by titration unless it is first reduced by hydrogen sulphide. Ascorbic acid in these three forms may be biologically active but only the free acid can be estimated by simple acid extraction and titration. Bovine adrenal tissue contains no ascorbic acid in the reversibly oxidised form. Acid fruits, such as lemons, oranges and tomatoes, apparently contain only free ascorbic acid.

## SUMMARY.

1. A series of modifications in the titration procedure of Harris and Ray which render the estimation of ascorbic acid more accurate have been described.

2. Two methods have been outlined for the removal of interfering plant pigments.

3. Vegetable tissues do not appear to contain a mechanism to prevent the aerobic oxidation of ascorbic acid. Hence they generally contain appreciable quantities of reversibly oxidised ascorbic acid.

4. Several vegetables show an increased titration value after heating for a short period, or after acid hydrolysis. The increase is believed to be due to the liberation of ascorbic acid from a compound which is soluble in water but insoluble in trichloroacetic acid.

It is a pleasure to acknowledge our indebtedness to Prof. C. H. Best, and to Dr J. G. FitzGerald. Miss Lillian Barber rendered valuable technical assistance.

# CCXXXV. PURIFICATION OF THE ACTIVE PHOSPHATASE FOUND IN DOG FAECES.

By ARTHUR RILEY ARMSTRONG.

*From the Department of Medical Research, Banting Institute,  
University of Toronto.*

*(Received July 1st, 1935.)*

It was observed [Armstrong *et al.*, 1934] that a phosphatase, active at  $p_H$  9.6, was present in dog faeces. The activity of the faeces is variable but usually exceeds that found in the case of intestinal mucosa which is the tissue having, weight for weight, the greatest phosphatase activity in the body.

It seemed worth while to attempt to isolate, if possible, a crystalline enzyme from this cheap and unlimited source. Whilst a crystalline material was not obtained, the degree of purification reached was sufficiently great to warrant publication in view of the fact that the work must now be temporarily abandoned.

The underlying principles involved in the procedures employed were as follows: preparation of a water-clear aqueous extract of the faeces, salting out the protein from this extract, solution of the protein and removal of foreign material by acidification and adsorption, reprecipitation of the protein with minimum contamination by inorganic salts. These procedures presented considerable difficulty for two reasons: (1) the colloidal nature of concentrated mixtures of faeces and water and (2) the fact that the phosphatase active at  $p_H$  9.6 is unstable in acid media. No difficulty was ever encountered owing to faecal extracts containing large amounts of unhydrolysed protein. The protein content was always less than 1% and a large part of this was insoluble in acid.

The procedure outlined below avoids the difficulties mentioned and makes possible the preparation of a dry powder of unusual potency within 48 hours.

## EXPERIMENTAL.

### A. *To obtain a water-clear filtrate from the faeces.*

About 1 kg. of dog faeces, collected within 24 hours of being passed, is placed in a 3 l. beaker. Cracked ice is placed in the beaker and tap water is added to make the total volume about 2 l. The contents are now stirred thoroughly until uniform. When completely mixed the coarse particles are removed by straining through three grades of wire sieve, the final one being 40-mesh.

The sludge is now cooled to 0° and 20 ml. glacial acetic acid are added, causing some of the phosphates to dissolve. The fluid is now brought to  $p_H$  (about) 8 by adding approximately 30 ml. concentrated ammonia. This causes the dissolved phosphates to precipitate and the precipitate entrains fine particles which otherwise will pass through a filter paper. The sludge is now poured into a pleated coarse filter-paper and left in the ice-box filtering overnight. The dark brown filtrate should be free from any turbidity. If turbidity is present the suspension must be filtered through a thin layer of diatomaceous earth under suction.

If kept near 0° this solution retains its phosphatase activity for some days.

*B. To obtain a washed protein-like precipitate from "A".*

To the ice-cold filtrate "A", ammonium sulphate is added to complete saturation. A precipitate forms which tends to rise.

A quarter volume of 65–70 % acetone is now stirred in. The precipitate rises rapidly and collects at the interface between the acetone and ammonium sulphate layers. This precipitate is skimmed off in a spoon and placed in a separating funnel. The saturated ammonium sulphate solution which accompanies it is drained through the stopcock, and the supernatant acetone decanted.

Successive amounts of 65 % acetone are added to the precipitate in the funnel, shaken and decanted; the supernatant liquid finally becomes nearly colourless. The precipitate is then run through the stopcock into a filter-paper and allowed to drain thoroughly. This material is greyish brown in colour and turns dark brown after exposure to air for a few minutes.

*C. Decoloration and purification of "B".*

The washed precipitate, "B", is dissolved in 100 ml. water kept at  $p_H$  8–9 with 1 % ammonia. It is brought to 0° and then adjusted to  $p_H$  4–4.5 with about 0.5 ml. glacial acetic acid. A variable amount of relatively inactive material precipitates.

1 g. of activated charcoal is shaken in. After 10 min. the mixture is filtered in the ice-box through a filter-paper prepared by filtering through it 100 ml. 1 % charcoal suspension. This latter technique prevents any fine charcoal particles, rendered semi-colloidal by the protein, from passing through the filter. Filtration takes from 0.5 to 12 hours, depending upon the physical state of the protein thrown down by the acid. The ice-cold filtrate is now brought to  $p_H$  7.0 by adding about 1 ml. strong ammonia solution.

*D. To obtain a dry powder nearly free from ammonium sulphate and other inorganic salts.*

To the neutralised filtrate, "C", acetone is added to make 60 % concentration. Most of the active material is precipitated and on standing much of the turbid supernatant fluid can be decanted. The residue is poured into a filter and allowed to drain thoroughly. It forms a gummy mass which is readily removed from the filter-paper. This is placed on a watch glass, dried in a vacuum desiccator overnight and ground to a fine powder. It is grey to faintly brown in colour.

*Yield and activity.*

There is a considerable variation in the yield of powder obtained. From an amount of faeces sufficient to occupy a volume of about 1 l. yields of 0.1–0.5 g. have been obtained. This is to be expected, for the amount of active material per g. of faeces will vary according to the amount of undigested material in the stool.

The activity of the powders has been estimated by the phenylphosphate method [King and Armstrong, 1934] with the modification that excess  $Mg^{++}$  ion was added to the buffered substrate. This was considered advisable since in the process of purification this co-enzyme is reduced to a trace. The activities of successive batches lay between 130,000 and 185,000 units per g. (For comparison it may be recalled that 1 g. wet weight of adult dog long bone has an activity of about 2 units by the same method.)

A clearer conception of the tremendous activity is obtained by the following computation based on the definition of a "unit", *viz.* that 1 g. of the best powder (185,000 units per g.) acting on an excess of disodium phenyl phosphate in the presence of Mg ion and in sufficient dilution in a buffer solution of suitable  $p_H$  at  $37.5^\circ$  will liberate 185 g. of phenol every 30 min., *i.e.* more than 6 g. per min.

The activity obtained is considerably diminished if the sludge and filtrates are not kept cool during the preparation, especially when the  $p_H$  is lower than 7.0. Allowing the solutions to stand for longer times than mentioned also causes some loss. Apart from these causes, variations in activity may be expected, if for any reason any protein-like material behaving chemically in a manner similar to the powder should be passed in the faeces. Apparently however such a material is not encountered in any considerable quantity.

*Optimum  $p_H$ .* Between  $p_H$  3.0 and 10.5 only one zone of optimum activity was observed when disodium phenyl phosphate was used as substrate. The optimum  $p_H$  lay approximately at 9.6 measured at  $37^\circ$ ; practically no activity was observed below  $p_H$  6.0. This suggests the identity of the enzyme with bone phosphatase.

*Enhancement of activity by  $Mg^{++}$  ions.* An increase in the activity of the enzyme using the buffered substrate of King and Armstrong [1934] occurred when  $Mg^{++}$  ions were added; approximately 0.0003 *M*  $Mg^{++}$  produced a 25 % increase. Further increases to 0.003 *M* produced no definite additional enhancement.

*Qualitative analysis.* On analysis the material was found to contain 2.7 % ash of which 0.24 % was silica. The powder gave qualitative tests for nitrogen and phosphorus; a trace of halogen was present and faint traces of sulphur and iron.

*Adsorption by kaolin.* The material may be adsorbed on kaolin and eluted with a recovery as high as 90 %. No attempt has been made to reprecipitate a powder from such a recovered solution. The conditions for adsorption and elution are as follows: 1 ml. of 0.5 % solution of phosphatase powder and 1 ml. 5 % kaolin suspension are brought to  $0^\circ$  and acidified with 1 % acetic acid to  $p_H$  4.5. The kaolin is quickly centrifuged, washed with ice-cold water at  $p_H$  5 and again quickly centrifuged. To the washed kaolin is now added 1 ml. of 0.5 % diammonium hydrogen phosphate and after stirring for 15 min. the kaolin is finally removed by centrifuging. The active material is now in the phosphate solution.

#### SUMMARY.

A method is described by which a very potent phosphatase-containing powder can be obtained from dog faeces within 48 hours. Its optimum  $p_H$  is in the region of 9.6 measured at  $37.5^\circ$  when acting on disodium phenyl phosphate. No other zone of optimum  $p_H$  has been found. Using the same substrate the optimum  $Mg^{++}$  ion concentration is below 0.0003 *M*.

I wish to express my thanks to Mr C. C. Lucas for several valuable suggestions and assistance, and to Sir Frederick Banting for advice and encouragement throughout this work.

# CCXXXVI. ON A FAT-SOLUBLE GROWTH FACTOR REQUIRED BY BLOW-FLY LARVAE.

## II. IDENTITY OF THE GROWTH FACTOR WITH CHOLESTEROL.

By RALPH PERCIVAL HOBSON.

*From the Department of Agricultural Zoology, School of Agriculture,  
University College of North Wales, Bangor.*

*(Received July 5th, 1935.)*

In the previous paper of this series [Hobson, 1935], it was shown that blow-fly larvae (*Lucilia sericata* Mg.) respond to a fat-soluble growth factor. Since there was evidence that the active substance might be cholesterol, further growth tests have been carried out with samples from various sources. The results of these experiments leave little doubt that the larval growth factor is cholesterol.

### METHODS.

The basal diet was the same as that used in the earlier experiments [Hobson, 1935]. It consisted essentially of a 15% peptone solution prepared from meat by digestion with pepsin and subsequent filtration. In addition, the preparations used in these experiments were extracted with ether to remove the last traces of fat. A small amount of aqueous yeast extract was added to the peptone solution so as to ensure a sufficiency of vitamin B. Cholesterol samples were tested in the following way. An emulsion was prepared by pouring an alcoholic solution into water and removing the alcohol by evaporation on a boiling water-bath. The emulsion was then filtered through cotton-wool and its sterol content determined by a dry weight estimation. Suitable mixtures of peptone solution and emulsion were prepared and 1 ml. lots absorbed on pieces of bandage in small test-tubes; three larvae were reared in each tube. Since fine emulsions could not be obtained with the other sterols, they were supplied as triolein solutions. The procedure adopted in this case was the same as that used in earlier experiments with different fats [Hobson, 1935]. In the present growth trials, the larvae were reared for 2½ days at 35°, then starved for 4 hours and weighed. A weight of 40 mg. was taken to represent satisfactory growth under these conditions.

### *Materials used.*

Table I describes the origin of the samples tested. This work was considerably facilitated by gifts of sterols. I take this opportunity of thanking Prof. J. C. Drummond, Mr A. L. Bacharach and Mr A. R. Freney for specimens respectively of purified cholesterol, sitosterol and wool sterols.

Table I. *Description of the sterol samples.*

Material	Method of preparation and purification
Purified cholesterol	Regenerated from dibromide
Brain cholesterol	Extracted with acetone; recrystallised from alcohol
Egg cholesterol	Non-sap. from technical ovoidlecithin; recrystallised from alcohol
Wool cholesterol	Separated from wool wax [Freney, 1934]
Lanosterol	
Sitosterol	Crude sterol from wheat germ oil non-sap.; recrystallised from alcohol
Ergosterol	Presumably derived from yeast

## RESULTS.

Preliminary trials with an emulsion of egg cholesterol showed that good growth occurred with 0.01 % of added sterol. The four samples were compared in two series, egg cholesterol being included in each. The results, given in Table II, show that the growth-promoting effect of cholesterol does not vary with the source and is not altered by chemical purification (conversion into bromide). It is, therefore, concluded that the active substance is not an impurity, but the sterol itself. It will be shown also that the potency of various fats can be correlated with their sterol content if allowance is made for the type of sterol. Other sterols stimulate growth but are less active than cholesterol (Table III).

Table II. *Effect of cholesterol on the growth of larvae on peptone diet.*

	Mean weight of 3-day old larvae (mg.).					
	% sterol on volume of peptone solution					
Sample	0.03	0.01	0.005	0.0025	0.001	0
Wool	—	43.45	32.34	20.22	—	Died <i>ca.</i> 1 mg.
Brain	—	39.43	35.36	18.24	—	
Egg	41, 44	39.44	36.37	25.27	—	
Egg	41, 47	38.48	37.40	22.27	9, 11	Died <i>ca.</i> 1 mg.
Purified	44, 49	44.40	32.38	24.28	7, 10	

Table III. *Effect of various sterols on the growth of larvae on peptone diet.*

	Dose mg.	Weight of 3-day old larvae mg.
Cholesterol	0.06	39, 41, 44
	0.03	33, 40, 44
	0.015	x, 26, 29
	0.007	x, x, 15
Sitosterol	0.12	41, 46, 48
	0.06	x, 26, 33, 37
	0.015	x, x, x
Ergosterol	0.12	31, 35, 45
	0.06	x, 25, 28
	0.015	x, x, x
Lanosterol	0.12	23, 32, 39
	0.06	x, x, x
Controls	0	x, x, x, x

x indicates larva dead on 3rd day.

The sterol was given in triolein.

Solutions of sterol in triolein were used in these tests; the amount of oil given was the same in each case, 6 mg., except for the higher doses of ergosterol and lanosterol which required more solvent. Since blow-fly larvae normally breed only in animal tissues, it is not surprising to find that they utilise cholesterol more readily than sterols from other sources.

*Growth under asepsis.*

The experiments already described were carried out with larvae from unsterilised eggs. It is, therefore, possible that the sterol is not the growth factor itself, but the precursor of an active substance produced by bacterial action. Aseptic growth trials showed that this is not the case. Larvae grew readily under aseptic conditions on the peptone diet supplemented only with cholesterol (sterility being confirmed by inoculation of nutrient media); also, they pupated and produced normal adults. Since the diet contained no fat whatever, these results suggest that blow-fly larvae can synthesise fat but not sterol. Analyses are being carried out to confirm this.

*Correlation between the sterol content and potency of natural fats and oils.*

Table IV shows that the growth-promoting effect of various fats and oils can be correlated with their sterol content. The potencies were calculated from the inverse of minimum active dose [Hobson, 1935], cholesterol being assigned

Table IV. *Correlation between the sterol content and potency of various substances.*

	% non-sap.	% sterol	Potency
Cholesterol	—	100	100
Wool wax	40	27	25
Wheat germ oil	5.8	3.5	1
Egg yolk	—	1.3	0.8
Cod-liver oil	0.8	0.4	0.5
Butter	0.3	—	0.4
Lard	0.3	—	<0.4
Olive oil	0.9	—	<0.4

the arbitrary value of 100. Since the samples used in the growth tests were no longer available, the figures for the contents of unsaponifiable matter and sterols were taken from published analyses: wool wax [Dorée and Garratt, 1933]; wheat germ oil [Drummond *et al.*, 1935]; cod-liver oil [Drummond *et al.*, 1925]; egg yolk, mean value from various sources; the remainder, average figures from analyses quoted by Lewkowitsch [1922]. It must be realised that these values are subject to variation and that the error in assaying the potency was probably not less than  $\pm 50\%$ .

When expressed in this way, the potency should equal the percentage of the sterol, if this is the active substance. It will be seen that the animal fats and oils show good agreement. The potency of the two vegetable oils tested is considerably less than their sterol content (assuming that sterols form about half of the unsaponifiable matter of olive oil, *i.e.* 0.4–0.5%); this is to be expected since the activity of the typical plant sterol, sitosterol, proved to be about a quarter of that of cholesterol.

*The effect of sterol on the immunity of larvae to bacterial infection.*

The absence of sterols from the diet, besides affecting the growth rate directly, also renders larvae susceptible to bacterial infection [Hobson, 1935]. The natural immunity of larvae seems to be due to an acid secretion in the intestine; normally, the gut contents are strongly acid in the middle part of the mid-gut, the function of the acidity probably being bactericidal action [Hobson, 1931]. It has been found that the acidity in the mid-gut is dependent upon the presence of cholesterol in the food. This observation explains the "anti-infective" action of cholesterol and also confirms the view that the acid serves as an antiseptic. An account of the actual experiments will be given in a later communication dealing with the nature of the acid secretion. It is of interest to note that the alleged bactericidal action of blow-fly larvae has led to their being used therapeutically in the treatment of chronic osteomyelitis. This question is also of importance in relation to the development of septicæmia in sheep infested with blow-fly larvae.

## DISCUSSION.

The results of the feeding tests show that the growth-promoting effect of cholesterol is the same for various samples, including one subjected to chemical purification. Also, the potency of natural fats and oils can be explained by their content of cholesterol or sitosterol. The sterol is not the precursor of a

vitamin formed by bacterial action, since the absence of bacteria does not affect its potency. It is, therefore, concluded that the fat-soluble growth factor required by blow-fly larvae is a sterol. Furthermore, a sterol is the only fat-soluble substance essential for larval growth, since the preparation of the basal diet was such as to remove all lipid matter. Blow-fly larvae, therefore, differ from higher animals; these can apparently dispense with sterols but need certain fatty acids in addition to vitamins occurring in the non-sterol fraction of the unsaponifiable residue.

It seems not improbable that a sterol may be an essential growth factor for insects generally; however, further investigation is clearly necessary before this question can be decided. The earlier work on the fat requirements of insects, reviewed in a previous paper [Hobson, 1935], shows no discrepancies between blow-fly larvae (Diptera) and other insects. In addition to *Drosophila* (Diptera), both *Blatta* (Orthoptera) and *Ephestia* (Lepidoptera) have been shown to respond to a fat-soluble growth factor (other than fat itself). If this substance is not a sterol, it follows that these insects require some "vitamin" which is not needed by blow-fly larvae, a hypothesis which seems very unlikely.

Since blow-fly larvae fail to grow without cholesterol, they presumably cannot synthesise this substance. However, this does not necessarily follow; yeast, for example, can synthesise bios and yet cannot develop in a medium completely lacking in bios. It is possible that blow-fly larvae can synthesise a part but not all of their sterol requirements. This question can only be settled by investigating the sterol balance. Bloor [1934], discussing the question of cholesterol synthesis, says: "It is now generally admitted that cholesterol can be synthesized by the animal organism." The evidence for this statement is based on experiments with higher animals; little appears to be known about the sterol metabolism of invertebrates.

#### SUMMARY.

1. Purified cholesterol supplies an essential growth factor required by blow-fly larvae.
2. The potency of cholesterol samples of different origin is the same, the minimum active dose being about 0.07% of the dry weight of the diet.
3. Ergosterol, lanosterol and sitosterol also promote larval growth, but are less active than cholesterol.
4. The potency of natural fats and oils can be correlated with their content of cholesterol or sitosterol.
5. It is concluded that the fat-soluble growth factor is the sterol itself.
6. Blow-fly larvae do not require fatty acids or fat-soluble vitamins present in the non-sterol fraction of the unsaponifiable residue.

I wish to record my thanks to the Agricultural Research Council for a grant which entirely financed this work.

# CCXXXVII. LIVER GLYCOGEN.

## II. ACYL DERIVATIVES AND "REGENERATED GLYCOGENS".

By DAVID JAMES BELL AND HANS KOSTERLITZ.

*From the Physiological Laboratory, Marischal College,  
The University of Aberdeen.*

(Received July 5th, 1935.)

THIS paper extends the observations of Bell and Young [1934] to the preparation and properties of acetyl and benzoyl derivatives of glycogens, the examination of the polysaccharides regenerated from these acyl derivatives and the occurrence of phosphorus in both the original and regenerated materials.

### *Acyl derivatives.*

The triacetates and tribenzoates of pure glycogens, isolated from rabbit and fish (*Gadidae*) livers as described by Bell and Young, were obtained in good yield. A comparison of the properties of these substances revealed no difference between derivatives from the two sources (Table I). It was noted that glycogen extracted by water (no KOH treatment) displayed resistance to acetylation. Preliminary heating with 30% KOH solution, however, was found to promote complete acylation.

Table I.

Source of glycogen	Acetate			Benzoate		
	Yield %	Acetyl %	$[\alpha]_D$	Yield %	Benzoyl %	$[\alpha]_D$
Rabbit (water-extracted)	50	43.9	+ 172°	—	—	—
„ (KOH water-extracted)	84	44.0	+ 171°	80.0	65.0	+ 113°
„ (water-extracted, after KOH)	84	44.0	+ 171	—	—	—
Fish (water-extracted)	Trace	—	—	84.7	66.4	+ 114
„ (water-extracted, after KOH)	87	44.4	+ 170	—	—	—

$[\alpha]_D$  was determined in chloroform solution.

### *The regenerated polysaccharides.*

De-acylation of the acetates and benzoates yielded theoretical amounts of materials which, at present, cannot but be considered as chemically identical with the parent substances. The results are summarised in Table II.

The rates of hydrolysis with 2.4% HCl at 100° (*vide* Bell and Young) were in all cases the same and were unchanged from those of the parent substances. Regeneration likewise did not affect the coloration with iodine, deep red-brown with rabbit glycogen and yellow-brown with the material from fish.

### DISCUSSION.

*Phosphorus content.* This is extremely small and diminishes after acylation. As no precautions were taken to employ phosphorus-free reagents, it is probable that the presence of this element in the highly purified materials is adventitious

Table II.

\* High value due to nitrogenous impurity.

(cf. Somogyi [1934] who has recently prepared phosphorus-free glycogen). There are, therefore, no grounds for believing that phosphorus is an integral constituent of glycogen.

*The regenerated glycogens.* The only observed differences between the regenerated and parent substances were (a) a slightly increased rotatory power and (b) an appreciable diminution in the opacity of the solutions, indicating a smaller colloidal particle after regeneration. It is very probable that the enhanced rotation arises from this condition, particularly as the post-regeneration polarimetric observations were made with much less difficulty.

The most significant fact arising out of this work is that glycogen does not appear to undergo degradative changes on acylation by the method here employed using pyridine and acetic anhydride. This has an important bearing on the experiments of Haworth and Percival [1932] who postulate a "chain-length" of 12 glucose units for glycogen, basing their assumption on the amount of tetramethylglucose obtainable from methylated glycogen. One of us [Bell, 1932] and Irvine [1932] have criticised Haworth's analogous deductions in the cases of cellulose and starch respectively, when the initial acetylation was carried out in an acid system; indeed Irvine and Caldwell (unpublished work) find that the reducing power of starch (Hanes's method) increases steadily as a result of acylation, even under mild conditions, and that the amount of tetramethylglucose obtainable from methylated starch varies within wide limits, according to the method of acetylation adopted. In the present instance, however, we believe that our findings support Haworth's conclusions regarding glycogen.

The values of the reduction of alkaline hypiodite, which Haworth and Percival [1932] found for their specimen of glycogen are in close agreement with ours; we, also, are unable to correlate reducing power with chain-length, as will be shown in a further communication from this laboratory.

## EXPERIMENTAL.

*Glycogen triacetates.* These were prepared according to the procedure of Haworth and Percival [1932].  $[\alpha]_D^{20}$  was determined in chloroform,  $l=1$ ,  $c=1$ .

(a) *H<sub>2</sub>O-extracted glycogen.* A 50% yield was the best obtained in two experiments. Much unchanged glycogen was recovered; this did not react with fresh acylating agents. The product showed  $[\alpha]_D^{20}+172.1^\circ$ . (Found: OAc, 43.9%.  $C_6H_7O_5(OAc)_3$  requires OAc, 44.7%.)

(b) *H<sub>2</sub>O-extracted glycogen after treatment with KOH.* 2 g. of material were heated for 2 hours at  $100^\circ$  with 30% KOH solution, neutralised with acetic acid and the glycogen precipitated by the addition of 2 volumes of 95% alcohol. The precipitate was washed with alcohol and ether and introduced into the acetylating mixture in which it rapidly dissolved. Yield 3 g. (84.3%);  $[\alpha]_D^{20}+170.9^\circ$ ; OAc, 44.0%.

(c) *KOH-extracted glycogen.* From 2 g. lots, two experiments gave the following yields:

3.00 g. (84.5%);  $[\alpha]_D^{20}+170.9^\circ$ ; OAc, 44.0%.  
3.01 g. (84.6%);  $[\alpha]_D^{20}+171.7^\circ$ ; OAc, 44.1%.

(d) *Fish glycogen (H<sub>2</sub>O-extracted).* As this material proved totally resistant to acetylation it was treated as (b). 1.90 g. yielded 2.97 g. acetate (87.4%);  $[\alpha]_D^{20}+170.2^\circ$ ; OAc, 44.4%.

*Glycogen tribenzoates.* The procedure was similar to that employed by Irvine and Caldwell (unpublished work) for the benzylation of starch, and was as follows. 1 g. glycogen was dissolved in 30 ml. 10% NaOH and shaken with 11 g. (9.3 ml.) benzoyl chloride. A white solid which separated was filtered off, washed with 10% NaOH and dried by alcohol-benzene under reduced pressure. The dry material was dissolved in 10 ml. dry pyridine and 3.5 ml. benzoyl chloride were added with cooling. After standing for 24 hours excess of alcohol was added and the semi-solid mass triturated with dilute HCl and then dilute NaOH, washed with water, then alcohol, dissolved in a mixture of 3 parts chloroform and 1 part acetone and precipitated by adding alcohol. Finally, the solid was dissolved in chloroform, shaken with norite and filtered through a Seitz filter. From the pale yellow, opalescent solution by the addition of alcohol the tribenzoate was obtained as a creamy solid, soluble in the usual organic solvents except alcohol, petroleum and ether.

(e) *Fish glycogen.* Yield 84.7%;  $[\alpha]_D^{20}+115.0^\circ$  ( $l=1$ ,  $c=0.6$ );  $+112.8^\circ$  ( $l=2$ ,  $c=0.5$ ) in  $CHCl_3$ . (Found:  $COC_6H_5$ , 66.35%.  $C_6H_7O_5(COC_6H_5)_3$  requires  $COC_6H_5$ , 66.45%.)

(f) *Rabbit glycogen.* Yield 80%;  $[\alpha]_D^{20}+113.4^\circ$  ( $c=1.0$ ,  $l=2$ ) in  $CHCl_3$ . (Found:  $COC_6H_5$ , 65.0%.)

*Regeneration of the carbohydrates.* The acetates were de-acetylated by allowing them to stand for 24 hours at room temperature in contact with a 50% excess of 50% aqueous methyl alcoholic 3% KOH. After acidifying with acetic acid, 2 volumes of alcohol were added and the resulting precipitate was washed with 66% alcohol and reprecipitated twice from water by 2 volumes of alcohol. The final product was examined by the procedure of Bell and Young, and in addition the hypiodite reducing values were determined by the method of Macleod and Robison [1929], and phosphorus, inorganic and organic, by the methods of Lohmann [1928] and Lohmann and Jendrassik [1926].

Owing to their insolubility in alcohol, the benzoates were dissolved, in 10% concentration, in acetone and shaken at room temperature for one hour with two-fifths volume of 20% KOH. The reaction was completed by warming at  $50^\circ$

for 10 min. The addition of 2 volumes alcohol rendered the gummy precipitate solid; this was reprecipitated three times from water (after acetic acid neutralisation) with 2 volumes alcohol.

The properties of the regenerated materials appeared little altered (Table II), except with regard to the opacity in solution. This was appreciably lessened in the case of material regenerated from the acetates and considerably so in that regenerated from the benzoates. The yields were theoretical.

#### SUMMARY.

Rabbit and fish (*Gadidae*) liver glycogens do not appear to undergo degradation when acetylated or benzoylated by the methods employed. Examination of the regenerated glycogens with respect to reducing power (ferricyanide and hypiodite), rotatory power and rate of hydrolysis with acid revealed no significant differences from the same properties of the original materials.

The organic phosphorus contents were very small and were diminished to even lower values on regeneration.

We desire to acknowledge with gratitude the award of a Senior Studentship of the Exhibition of 1851, and a grant from the Royal Society to one of us (D. J. B.). We are also indebted to Sir J. C. Irvine for his continued interest.

# CCXXXVIII. LIVER GLYCOGEN.

## III. THE MOLECULAR UNITS OF FISH AND RABBIT GLYCOGENS.

By DAVID JAMES BELL.

*From the Physiological Laboratory, Marischal College,  
The University of Aberdeen.*

*(Received July 25th, 1935.)*

IN continuation of investigations in progress in this laboratory, glycogens from rabbit and fish livers, purified by the method of Bell and Young [1934], have been subjected to methylation according to Haworth and Percival [1932]. Although preliminary acetylation is thus involved, Bell and Kosterlitz [1935] have shown that it is unaccompanied by degradation, and it is therefore concluded that true methylated glycogens are obtained in this way. Hydrolysis of these derivatives, followed by quantitative separation and investigation of the cleavage products, revealed complete chemical identity of the two glycogens derived from widely different sources, although Bell and Young previously found a distinction in respect of the coloration developed with iodine.

Both glycogens, when fully methylated, showed OMe 45·4–45·5 %, values which were not raised by repeated treatment with dimethyl sulphate, although, as will be seen, the substances were not completely etherified. It was found impossible to apply the liquid ammonia method of methylation owing to insolubility of the materials in that medium. The properties of the two products were identical (see below) and both gave, in aqueous solution, a deep reddish brown coloration with iodine, indistinguishable from that of pure rabbit liver glycogen.

After hydrolysis, separation of the cleavage products yielded, in both cases, analytically pure tetramethylglucopyranose, in amount over 9 % of the starting-material, indicating on the basis of Haworth and Percival's formula, a molecular magnitude approximating to 12 glucose units. The bulk of the cleavage products was 2:3:6-trimethylglucose, uncontaminated by isomerides; and in addition about 15 % of dimethylglucose. That this arose from the presence of unetherified hydroxyl groups present in the methylated glycogen, and not from the elimination of side-chains by hydrolysis, was shown by treating methylated glycogen (a) with nitrogen pentoxide in dry chloroform and (b) with dichloroacetyl chloride in dry pyridine at  $-10^{\circ}$  [Bell, 1935] whereby nitrate was introduced by (a) and dichloroacetyl by (b).

Table I records the general results of the investigation—rabbit glycogen being investigated with respect to two separate preparations.

### DISCUSSION.

The methods employed in this work lead to excellent recovery of cleavage products. The amounts of dimethylglucoses obtained assist considerably in assessing the molecular magnitude of these glycogens, since change in chain-length and degree of methylation alters the ratios, trimethylglucose/tetramethylglucose and trimethylglucose/dimethylglucose, indicated by examples in Table II.

Table I.

The values in parentheses indicate theoretical yields calculated on the basis that methylated glycogen gives, on cleavage, 1 mol. tetra-, 9 mols. tri- and 2 mols. di-methylglucose.

	Rabbit glycogen		Fish glycogen III
	I	II	
$[\alpha]_D$ in $\text{CHCl}_3$	+208.5°	+208.7°	+208.5°
$[\alpha]_D$ in $\text{H}_2\text{O}$	—	+208.0°	+207.7°
Amount of material hydrolysed (g.)	19.34	20.43	27.052
Yield of tetramethylglucose (g.)	1.806 (1.851)	1.852 (1.955)	2.480 (2.590)
„ trimethylglucose (g.)	15.425 (15.680)	15.856 (16.550)	20.832 (21.940)
„ dimethylglucose (g.)	3.155 (3.360)	3.000 (3.445)	4.094 (4.565)
% recovery of cleavage products	97	94	93
% of starting material as tetramethylglucose	9.3	9.0	9.2
No. of $\text{C}_6$ chains in molecular unit of glycogen	12	12	12

Table II.

			No. of molecules of cleavage products			Ratios, by weight		
			A	B	C	B/A — B/C		
	No. of C <sub>6</sub> units in chain	No. of free OH groups	OMe %	Tetra- methyl- glucose	Tri- methyl- glucose	Di- methyl- glucose		
1	12	1	46.3	1	10	1	9.4	10.6
2	12	2	45.3	1	9	2	8.5	4.8
3	12	3	44.2	1	8	3	7.8	2.9
4	13	2	45.2	1	10	2	9.4	5.3
5	13	3	44.4	1	9	3	8.5	3.2
6	11	1	45.2	1	9	1	8.5	9.6
7	11	2	44.1	1	8	2	7.8	4.3
Found:	I	OMe %	45.4	Ratio B/A	8.5	Ratio B/C	4.4	
	II	"	45.5	"	8.6	"	5.3	
	III	"	45.5	"	8.4	"	5.0	

The only values which correspond closely to those found are afforded by the cleavage products of a dodecasaccharide in which 36 of the 38 OH groups are etherified (including the reducing group), the free OH groups existing each in a different  $\text{C}_6$  unit (line 2, Table II). The glucose units are united in an unbranched chain, since the OH groups were proved to exist as such in methylated glycogen, by the introduction of nitrate and of dichloroacetyl.

These results, besides fully substantiating the conclusions of Haworth and Percival regarding rabbit liver glycogen, further disclose the biologically interesting fact of the chemical identity of rabbit and fish liver glycogens.

#### EXPERIMENTAL.

*Methoxyl estimations* were made by an apparatus and reagents carefully calibrated by means of pure substances of known composition, when a straight-line relationship was shown to exist between the found and true values, by which those stated in this paper are corrected.

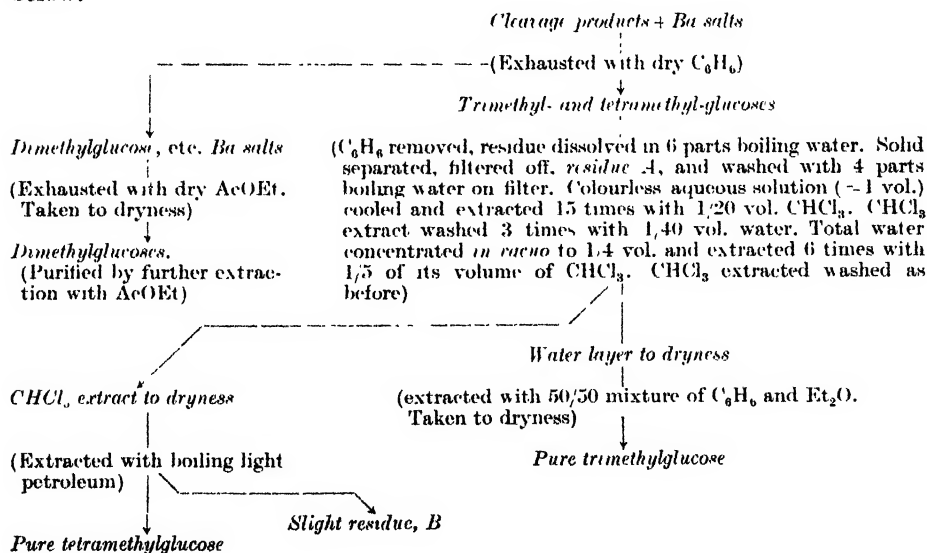

*Methylation of the glycogens.* This was effected by Haworth and Percival's modification for glycogen of the process of simultaneous deacetylation and methylation originally used by Irvine and Robertson [1926]. The acetates here

employed have already been described by Bell and Kosterlitz [1935]. Yields were excellent and the derivatives were obtained as white solids after precipitating several times from acetone solution by light petroleum (b.p. 60–80°) and evaporating a centrifuged acetone solution of the precipitate to dryness under reduced pressure. The methoxyl contents attained maximum values after 8 to 10 methylations and in each instance 8 further methylations proved ineffective in increasing them.

The three preparations (rabbit, I and II, fish, III) were all soluble in acetone, chloroform, benzene, pyridine, glacial acetic acid and cold water. In this last solvent all gave with iodine a red-brown coloration indistinguishable from that of rabbit glycogen.

By dissolving in cold water and raising the temperature to 80–90° the methylated glycogens were completely precipitated and could in this way be easily freed from any appreciable amount of ash. The rotatory powers are detailed in Table 1. (OMe found: I, 45.4; II, 45.5; III, 45.5 %.)

*Hydrolysis by aqueous acid and separation of the cleavage products.* An initial difficulty was provided by the insolubility of methylated glycogen in hot water; hydrolysis, however, was easily effected by adding 5 parts of glacial acetic acid to 1 part of methylated glycogen and reducing the pressure inside the flask so as to permeate the solid with solvent, then adding 10 parts 5 % HCl and heating on the water-bath; the solid rapidly dissolved to give a yellow solution. Heating was continued until a constant polarimetric reading was obtained. Barium carbonate, 10 % in excess of the HCl used, was then added and the whole evaporated to complete dryness under reduced pressure below 50°, water being added from time to time to facilitate removal of acetic acid. The residue was finally dried by alcohol-benzene, and worked up as described diagrammatically below.

It should be noted that Macdonald [1935] has recently substantiated the applicability of chloroform-water extraction to the quantitative separation of tetramethyl- from trimethyl-glucoses, and that the author has long been accustomed to effect quantitative separations in this manner. He has been

aware that trimethyl-sugars, if present in sufficient concentration, are extracted by chloroform, but also that washing with water removes them from the chloroform layer. Accordingly, the procedure adopted to separate approximately 10% of the tetramethylglucose from a mixture of lower homologues is included in the above scheme. In this manner the cleavage products from glycogens I, II and III, yielded analytically pure, largely crystalline 2:3:4:6-tetramethyl- and 2:3:6-trimethyl-glucose, and syrupy dimethyl-glucoses as indicated in Table III.

Table III.

Methylated glycogen	I	II	III
Amount hydrolysed, after deducting residue A	19.340 g.	20.430 g.	27.052 g.

M.P. after draining on tile	80–88°	87°	87°
Mixed m.p.	No dep.	No dep.	No dep.
2:3:6-Trimethylglucose:			
Amount found	15.425 g.	15.856 g.	20.832 g.
$n_D^{18^\circ}$ of fused substance	1.4750	1.4755	1.4750
$[\alpha]_D^{18^\circ}$ in water	+69.8°	+70.0°	+69.8°
$[\alpha]_D^{18^\circ}$ in water of authentic material	+70°	+70°	+70°
OMe (%)	41.8	41.9	41.9
Theoretical OMe (%)	41.9	41.9	41.9
M.P. after draining on tile	117°	115–118°	110–113°
Mixed m.p.	No dep.	No dep.	No dep.
Dimethylglucose:			
Amount found	3.155 g.	3.000 g.	4.094 g.
$n_D^{18^\circ}$	1.4850	1.4860	1.4850
OMe (%)	30.0	29.7	30.0
Theoretical OMe (%)	29.8	29.8	29.8

The dimethylglucose was proved to be homogeneous by converting it into the glucoside, which distilled in one fraction leaving no residue. Acetylation of the barium residues yielded no appreciable amounts of material, showing that monomethylglucose and glucose itself were absent from the cleavage products.

*Residues A and B.* Residue B was always too small in amount to be investigated, but residue A from glycogens I and III was examined in respect of  $[\alpha]_D$  and OMe. The substances were obtained in small amount, 19.925 g. of I giving 0.585 g. ( $[\alpha]_D$  (in  $\text{CHCl}_3$ ) +160°; OMe, 35%) and 27.936 g. of III giving 0.884 g. ( $[\alpha]_D$  (in  $\text{CHCl}_3$ ) +158°; OMe, 34%).

*Detection of free hydroxyl groups in fully methylated glycogen.* Treatment at 0° of a dry chloroform solution of methylated glycogen with a 30% solution of nitrogen pentoxide in chloroform for 2 min., introduced nitrate groups, as shown by a strongly positive diphenylamine reaction. In addition, approximately two dichloroacetyl groups could be introduced by the action of dichloroacetyl chloride in pyridine at -10°. (Found: Cl, 4.6;  $\text{C}_{72}\text{H}_{82}\text{O}_{62} \cdot (\text{CH}_3)_{36} \cdot (\text{C}_2\text{HOCl}_2)_2$  requires Cl, 5.2%.) The solubilities and outward appearance of these derivatives were unchanged from the parent materials.

## SUMMARY.

Fish and rabbit liver glycogens, investigated by the methylation method, were shown to have the same chemical structure. Hydrolysis of the fully methylated glycogens (OMe, 45.5%) followed by quantitative separation of the cleavage products (obtained in over 93% yield) into analytically pure tetramethylglucopyranose, 2:3:6-trimethylglucose and dimethylglucoses showed that both kinds of glycogen are built up of unbranched chains of 12 glucose units.

The author is indebted to the Commissioners for the Exhibition of 1851 for the award of a Senior Studentship. He further acknowledges the assistance provided by grants from the Royal Society and the Medical Research Council.

# CCXXXIX. THE INHIBITION OF RESPIRATION BY CYANIDE.

BY WILLIAM EDWARD VAN HEYNINGEN.<sup>1</sup>

*From the Biochemical Laboratory, Cambridge.*

*(Received July 13th, 1935.)*

DIXON AND ELLIOTT [1929] published a communication on the effect of cyanide on the respiration of animal tissues in which they claimed to have found that the maximum inhibition of respiration of animal tissues (kidney, liver, spleen) by cyanide was only 30–90 %. ALT [1930], working in Warburg's laboratory with Ringer-*M*/40 bicarbonate- $\text{CO}_2$  (0.03–0.05 atm. press.) medium, claimed to have found practically complete inhibition with animal tissues. He ascribed the low values of Dixon and Elliott to the influence of their medium, which had too high a phosphate concentration and a zero  $\text{CO}_2$  pressure.

It was with a view to a closer investigation of the influence of the phosphate, bicarbonate, and  $\text{CO}_2$  concentrations on respiration and on its inhibition that I carried out the following experiments.

## I. METHODS.

Respiration was measured by Warburg's method as described by Dixon [1934]. The manometer flasks used were conical with an inner cup for retaining the solution for absorbing respiratory  $\text{CO}_2$ . The medium used was that of Krebs [1933], modified in so far as it now contained  $10^{-2}M$  phosphate. In order to make the measurements more accurate, large amounts of tissue were used when dealing with a high concentration of cyanide and an organ with a low oxygen uptake. Thus, for instance, with ox spleen and  $10^{-2}M$  HCN it was necessary to use as much as 73 mg. dry weight of tissue, whilst 3.5 mg. were sufficient when no poison was used with rat kidney. It was found, however, both by Dixon and Elliott and by myself that respiration was independent of the volume in which the tissues were suspended. After each experiment the tissues were washed, dried at  $100^\circ$  to a constant weight and weighed. The oxygen consumption is expressed by the quotient  $Q_{\text{O}_2}$ , which is  $\frac{\mu\text{l. O}_2 \text{ per hour}}{\text{dry wt. of tissue}}$ . All measurements were made at  $37.5^\circ$ .

### *Technique of HCN poisoning.*

Cyanide poisoning is reversible and therefore it is essential to prevent the KOH in the inner cup from absorbing HCN. Krebs [1935] has recommended certain solutions containing varying proportions of KCN and KOH which are so adjusted as to have a concentration of free HCN equal to that in the outer cup. When HCN (which was prepared by neutralising pure KCN with HCl) was used a KCN–KOH solution with a corresponding free HCN concentration was placed in the inner cup of the manometer vessel. This absorption is accelerated by the small squares of filter-paper which are always placed in the inner cups.

That these precautions are essential is clear from the figures in Table I, in which the results of experiments with KCN–KOH mixtures and KOH alone are recorded.

<sup>1</sup> Sir Donald Currie Memorial Research Student.

Table I. *Showing the effect of absorption of HCN by KOH.*

Rat kidney slices with 0.5 % glucose substrate.

Concentration of cyanide	KCN-KOH in inner cup		KOH alone in inner cup	
	$Q_{O_2}$	% inhibition	$Q_{O_2}$	% inhibition
No HCN	—	—	—	—
$10^{-4} M$ HCN	— 19.4	2.0	— 19.8	—
$10^{-3} M$ HCN	— 4.0	79.9	— 23.5	0.0
$10^{-2} M$ HCN	— 3.1	84.3	— 18.3	7.5
			— 6.1	69.1

This absorption of HCN will probably account to some extent for the low degree of inhibition found by Dixon and Elliott, and by Alt when he repeated their experiments, since these workers did not take the precautions described above. It may also be possible that the values found by Banga *et al.* [1931] for the inhibition of the respiration of pig heart muscle are too low.

## II. INFLUENCE OF MEDIUM.

### *Influence on respiration.*

Dickens and Simer [1931] have found that the respiration of a variety of tissues is the same in bicarbonate-saline medium as in phosphate-saline medium. Dixon and Elliott, however, used a pure phosphate buffer as medium in which the concentration was  $M/10$ , whereas the phosphate concentration in the medium of Dickens and Simer was  $M/40$ . The great variations and low values of Dixon and Elliott's figures for the respiration of various animal tissues suggest that a high phosphate concentration is harmful.

I carried out a number of experiments in which the respiration and its inhibition of rat liver and kidney slices were measured in Dixon and Elliott's medium and in the medium described in section I. The results of these experiments are recorded in Table II.

Table II. *Showing the influence of medium on respiration and on its inhibition by cyanide.*

Tissue	Concentration of cyanide	Pure phosphate medium		Saline medium	
		$Q_{O_2}$	% inhibition	$Q_{O_2}$	% inhibition
Rat liver	Control	— 8.8	—	— 11.1	—
	$10^{-4} M$	— 7.3	17.0	— 9.9	10.7
	$10^{-3} M$	— 2.5	71.6	— 2.1	81.1
	$10^{-2} M$	— 2.0	77.2	— 1.8	83.8
Rat liver	Control	— 7.9	—	— 10.4	—
	$10^{-4} M$	— 8.3	0.0	— 8.5	18.2
	$10^{-3} M$	— 3.4	57.0	— 2.1	79.9
	$10^{-2} M$	— 3.2	59.5	— 2.0	80.8
Rat kidney	Control	— 11.4	—	— 19.0	—
	$10^{-3} M$	— 2.4	79.9	— 2.9	84.7
	$10^{-2} M$	— 2.2	80.8	— 1.9	90.0

These figures show that the respiration in pure phosphate medium is lower than in saline medium with  $M/40$  phosphate. Thus the respiration in phosphate medium for the two cases of rat liver and the one case of rat kidney is 79, 74 and 60 % respectively of the respiration in saline medium.

*Influence on degree of inhibition.*

In Table II it will be seen that with  $10^{-2}M$  HCN the absolute values for the  $Q_{O_2}$  are very nearly the same in both media.  $M/10$  phosphate inhibits the same part of the respiration as is affected by cyanide. The consequence is that the degree of inhibition is less.

## III. MEASUREMENTS OF INHIBITION BY CYANIDE.

The respiration of several different organs and its inhibition by varying concentrations of cyanide were now measured. I found that the degree of inhibition increases rapidly with increasing concentrations of cyanide up to a concentration of  $10^{-3}M$ . At this stage the degree of inhibition ranges from about 75 to 85%. It is only very slightly increased by a further tenfold increase in cyanide concentration. The percentage inhibition is plotted against molar concentration of HCN in the typical curves in Fig. 1. The results of these experiments are recorded in Table III.

Fig. 1. Degree of inhibition produced by increasing concentrations of cyanide.

The degree of inhibition by  $10^{-2}M$  HCN varies with different tissues and with different substrates from about 80 to 90%. An exception is seen in the case of Exp. 15 (guinea-pig kidney with pyruvate substrate), where the inhibition with  $10^{-2}M$  HCN is only 46%. This is probably due to a reaction between pyruvic acid and the HCN (formation of cyanohydrin?).

## IV. DISCUSSION.

Alt (see also Warburg [1931]) measured the inhibition of respiration of tissue slices suspended in bicarbonate-saline- $CO_2$  medium and found that there was an increase in degree of inhibition with increasing concentration of cyanide, reaching practically complete inhibition at a concentration of  $10^{-2}M$ . The production of lactic acid in the bicarbonate medium, however, would complicate the measurement of respiration. The low respiration associated with a high concentration of cyanide would be difficult to measure accurately, and it is possible that the difference between the results as found by his method and by mine is not real.

Table III. *Respiration, and its inhibition by cyanide, of various tissues.*

No.	Tissue	Added substrate	No HCN $Q_{O_2}$	$10^{-4}M$ HCN $Q_{O_2}$	$10^{-3}M$ HCN $Q_{O_2}$	$10^{-2}M$ HCN $Q_{O_2}$	% inhibition ( $10^{-2}M$ HCN)
1	Sheep liver	0.5% glucose	- 2.6	- 2.4	- 0.55	- 0.57	78.1
2	Sheep kidney	0.5% glucose	- 14.0	- 9.8	- 2.1	- 1.8	87.1
3	Ox liver	0.5% glucose	- 1.8	- 1.4	- 0.86	- 0.7	61.1
4	Ox spleen	$10^{-2}M$ lactate	- 4.1	- 3.0	- 0.95	- 0.83	79.8
5	Ox spleen	None	- 3.8	- 3.0	- 0.98	- 0.84	77.9
6	Rat intestine	0.5% glucose	- 7.5	- 6.6	- 1.9	- 1.6	78.7
7	Rat brain cortex	0.5% glucose	- 15.0	- 9.8	- 2.6	- 1.6	89.3
8	Rat kidney	$10^{-2}M$ lactate	- 33.0	- 24.7	- 7.3	- 4.2	87.3
9	Rat kidney	None	20.6	- 18.7	- 3.1	- 2.2	89.3
10	Rat kidney	None	- 19.0	—	- 2.9	- 1.9	90.0
11	Rat kidney	0.5% glucose	- 19.8	- 19.4	- 4.0	- 3.1	84.3
12	Rat testis	0.5% glucose	- 8.0	- 5.8	- 1.3	- 1.0	87.5
13	Rat liver	None	- 10.4	- 8.5	- 2.1	- 2.0	80.8
14	Rat liver	None	- 11.1	- 9.9	- 2.1	- 1.8	83.8
15	Guinea-pig kidney	$10^{-2}M$ pyruvate	- 14.7	- 15.2	- 13.0	- 7.9	46.2
16	Guinea-pig kidney	None	- 13.0	- 12.7	- 2.7	- 2.3	82.3
17	Guinea-pig kidney	0.5% glucose	- 16.7	- 14.3	- 7.9	- 1.8	89.2

The low degree of inhibition observed by Dixon and Elliott is probably due to the combined effect of the two factors already discussed, namely the removal of HCN by the KOH in the inner cup and the inhibition of respiration by the high phosphate concentration of their medium.

As shown in Exps. 4 and 5 in Table III, the respiration of ox spleen is inhibited about 80% by  $10^{-2}M$  HCN and 25% by  $10^{-4}M$  HCN. This is not in agreement with the finding of Dixon and Elliott that there was no inhibition of the respiration of this tissue with as much as  $3 \times 10^{-2}M$  HCN.

#### V. SUMMARY.

The respiration of liver, kidney and spleen slices suspended in  $10^{-2}M$  phosphate-saline medium is inhibited to the extent of 75–85% by  $10^{-3}M$  HCN and 80–90% by  $10^{-2}M$  HCN.

The discrepancy between these results and those of other workers—especially the low values found by Dixon and Elliott—has been investigated.

The thanks of the author are due to Dr H. A. Krebs, who suggested the investigation, for his constant help and advice; and to Sir F. G. Hopkins for his kindness and encouragement.

# CCXL. THE LINKAGE OF CHEMICAL CHANGES IN MUSCLE EXTRACT.

BY DOROTHY MOYLE NEEDHAM  
AND WILLIAM EDWARD VAN HEYNINGEN.<sup>1</sup>

*From the Biochemical Laboratory, Cambridge.*

*(Received July 20th, 1935.)*

THIS work was started as a result of the first paper of a series by Parnas *et al.* [1934] on the inhibition of ammonia production resulting from addition of phosphoglyceric acid to muscle "brei" poisoned with iodoacetate. Lohmann [1934] had shown that in dialysed muscle extract adenylic acid reacts with phosphocreatine to give adenylypyrophosphate; Parnas and his colleagues pointed out that muscle deaminase attacks only adenylic acid, not adenylypyrophosphate. They argued therefore from the  $\text{NH}_3$  inhibition that synthesis of phosphocreatine had taken place at expense of the energy and the phosphate of phosphoglyceric acid breakdown, and had been followed by conversion of adenylic acid into adenylypyrophosphate by Lohmann's reaction. Since that time they [Parnas *et al.*, 1935, 1] have actually demonstrated in this muscle "brei" an increase in phosphocreatine (especially when creatine is added), and an increase in adenylypyrophosphate, accompanying the ammonia inhibition. In Parnas's experiments the iodoacetate prevented the breakdown of the carbohydrate of the "brei" by inhibiting the dismutation of dihydroxyacetonephosphate to give glycerophosphate and phosphoglyceric acid [Meyerhof and Kiessling, 1933, 1. Embden and Deuticke, 1934; Ostern, 1934]. Barrenschcen and his colleagues [1935] have also shown that, during the disappearance of phosphoglyceric acid from muscle "brei" or extract, there is an increase in easily hydrolysable organic P, although, apart from showing some increase in phosphopyruvic acid, they did not identify the compounds formed.

Our own work was carried out on dialysed muscle extracts, which have the advantage of containing no carbohydrate or carbohydrate breakdown products, so that the addition of any poison is unnecessary in showing the effect of added phosphoglyceric acid. The extract can also be obtained free from creatine, adenylic acid, adenylypyrophosphate and magnesium, and the effect of adding any of these can be observed. A preliminary report of the present work was sent to *Nature* [Needham and van Heyningen, 1935]; a few days before this was published a preliminary account of similar results with dialysed muscle extracts by Ostern *et al.* [1935, 1] appeared, and shortly afterwards Meyerhof and Lehmann [1935] described similar work.

## TECHNIQUE.

*Preparation of extracts.* The frog muscle extract was made as described by Meyerhof [1926], by crushing the muscles in water at 0°. For the rabbit muscle extract, the animal was anaesthetised with Numal Roche, killed by bleeding and skinned; the hind limbs were cooled in ice, then the muscle was removed, minced in a cooled mincer, and mixed with 3 vols. of ice-cold water, being

<sup>1</sup> Sir Donald Currie Memorial Research Student.

allowed to extract for 30 min. before straining and centrifuging. Dialysis was carried out in a cellophane bag, holding 15–30 ml. extract, which was arranged to move slowly backwards and forwards in the vessel containing 5 litres of ice-cold 0.5% KCl solution. The KCl solution was kept well stirred.

The extracts were buffered with varying amounts of phosphate and bicarbonate. In Exps. 1 and 2 the  $p_H$  was about 9.0; in the later experiments it was always maintained at 7.2 by bubbling nitrogen containing 5%  $CO_2$  through the bicarbonate-containing mixture.

The barium was removed from the barium adenylypyrophosphate and barium phosphoglycerate before adding to the extract. This was done by dissolving in as little HCl as possible, adding the calculated quantity of sodium sulphate, spinning off the precipitate and neutralising.

*Methods of analysis.* All the phosphate estimations were done by Fiske and Subbarow's [1929] method. The separation of the phosphocreatine fraction, with soluble calcium salt, from the free phosphate and adenylypyrophosphate was made by means of Fiske and Subbarow's  $CaCl_2-Ca(OH)_2$  reagent. Pyrophosphate values were found by 7 minutes' hydrolysis in *N* HCl at  $100^\circ$ ; the difficultly hydrolysable phosphate (phosphoglyceric acid-P) was found by taking the difference between the total acid-soluble phosphate and the free phosphate after 2 hours' hydrolysis at  $100^\circ$  in *N* HCl (an allowance must be made for some adenylic acid-P unhydrolysed after 2 hours). All these hydrolyses were done in tubes fitted with water condensers. Total P was estimated by the method of Eggleton and Eggleton [1929–30]. Lactic acid was estimated by the method of Friedemann *et al.* [1927], and pyruvic acid by Case's [1932] method with one modification (for which we are indebted to Prof. A. Szent-Györgyi). After the formation of the dinitrophenylhydrazones, the excess of dinitrophenylhydrazine is removed by addition of 1 ml. of 10%  $NaNO_2$  solution to each 25 ml. sample. Without this precaution, high blanks were always obtained. After 1 minute's action of the  $NaNO_2$  the extraction with ethyl acetate is begun; with longer delay the hydrazones may be acted upon, and low pyruvic acid values result.

The samples of extract were as a rule deproteinised by running into trichloroacetic acid of such a strength that the final concentration of trichloroacetic acid was 4%; where phosphocreatine estimations were to be done, the sample and the acid were cooled to  $0^\circ$  before mixing. Where lactic acid was to be estimated, protein was removed with phosphotungstic acid. All experimental results are expressed in mg.

*Preparation of barium adenylypyrophosphate.* This was made from rabbit muscle according to the shorter method (method *a*) described by Lohmann [1931, 1]. The barium precipitate was twice redissolved in acid and reprecipitated with alcohol and barium acetate, and the final precipitate was washed many times with 50% alcohol. The resulting salt was 97.5% pure. For the adenylic acid used we are indebted to Dr P. Ostern, and for the barium salt of phosphoglyceric acid to Prof. O. Meyerhof and Prof. C. Neuberg.

#### SYNTHESIS OF PHOSPHOCREATINE.

Two typical experiments to show the conditions under which phosphocreatine may be synthesised in frog muscle extract are given below.

*Exps. 1 and 2.* In each case the extract stood 1 hour at room temperature and was dialysed 5 hours at  $0^\circ$ . It was made 0.04 *M* with regard to bicarbonate and 0.03 *M* with regard to phosphate. 1 ml. extract was made up to 2 ml.; each sample contained 0.38 mg. phosphoglyceric acid-P and 0.1 mg. Mg as  $MgCl_2$ . All stood 1 hour at room temperature. (See Table I.)

Table I.

	Inorganic P	Change in inorganic P	Phospho-creatine-P
<i>Exp. 1.</i>			
Without addition	0.880	—	0
+ 2 mg. creatine	0.853	- 0.027	0
+ adenylypyrophosphate containing 0.023 mg. pyrophosphate-P	1.090	+ 0.210	0
+ 2 mg. creatine + 0.4 mg. adenylic acid	1.090	+ 0.210	0.067
<i>Exp. 2.</i>			
Without addition	0.690	—	0
+ 6 mg. creatine	0.660	- 0.030	0
+ 0.4 mg. adenylic acid	0.880	+ 0.190	0
+ 6 mg. creatine + 0.4 mg. adenylic acid	0.850	+ 0.160	0.054

These experiments show: (a) That phosphoglyceric acid is broken down, with production of inorganic phosphate, when either adenylic acid or adenylypyrophosphate is present. (b) That the presence of creatine, in the absence of these adenylic compounds, does not assist breakdown. (c) That when breakdown occurs, provided creatine is present, phosphocreatine is synthesised.

These dialysed frog extracts did not show great activity, and the experiments were repeated and extended, using rabbit extract.

*Exp. 3.* The extract stood 1 hour at 20°, then was dialysed for 4 hours at 0°. It was made 0.032 *M* with regard to bicarbonate and 0.01 *M* with regard to phosphate. For each sample 4 ml. of the alkaline extract were used and made up with the various additions to 8 ml. Each sample had 0.6 mg. Mg. All stood 1 hour at room temperature. (See Table II.)

Table II.

A = + 24 mg. creatine + 1.6 mg. adenylic acid + 1.1 mg. phosphoglyceric acid-P.  
 B = + 24 mg. creatine + 1.6 mg. adenylic acid.  
 C = + 24 mg. creatine + 1.1 mg. phosphoglyceric acid-P.  
 D = + 1.6 mg. adenylic acid + 1.1 mg. phosphoglyceric acid-P.

	Inorganic P	Phospho-creatine-P	Pyrophosphate-P	(2 hours' hydro-lysable P) - (7 min. hydrolysable P)	Difficultly hydro-lysable P	Total P
A	2.10	0.320	0.384	0.112	0.448	3.36
A	1.89	0.000	0.032	0.112	0.240	2.27
C	2.08	0.496	0.080	0.352	0.304	3.31
D	2.08	0.016	0.384	0.256	0.576	3.46

This experiment shows: (a) The disappearance of phosphoglyceric acid-P; in A only 19%, in C only 13% and in D only 30% remained at the end of the time. (Allowance was made in A and D for the adenylic P unhydrolysed in 2 hours, about 60%.) (b) The very slight increase in inorganic P accompanying the breakdown. (c) The large increase in phosphocreatine, especially in C. This last fact is probably to be explained by incomplete removal of the adenylic acid of the extract by deamination and dialysis, as rabbit extract is well known to retain its activity much longer than frog extract [Lohmann, 1931, 2]. In A, where extra adenylic acid was added, this has probably reacted with some of the phosphocreatine formed, with the result that the phosphocreatine content is decreased. The incompleteness of the dialysis is further shown by the formation of a small amount of phosphocreatine in D, where no creatine was added. (d) The synthesis of adenylypyrophosphate. The fact that a synthesis, though small, has gone on in C confirms the view that adenylic acid is present in this sample; in A and D an amount of adenylypyrophosphate equivalent to the whole of the adenylic acid added has appeared.

In A 61%, in C 50% and in D 33% of the phosphoglyceric acid-P appears as phosphocreatine-P + adenylypyrophosphate-P, whilst only about 18% appears in each as inorganic P.

There seems to be no phosphopyruvic acid present, as the pyruvic acid concentration was not altered by 1 hour's hydrolysis in *N* acid at 100°.

*Exp. 4.* Another experiment was made with extract which stood 2 hours at 37° and was dialysed 6 hours at 0°. Samples were prepared as in Exp. 3, except that 1.3 mg. phosphoglyceric acid-P were added in each case. (See Table III.)

Table III.

	Inor- ganic P	Phospho- crea- tine-P	Pyro- phos- phate-P	(2 hours' hydro- lysable P) - (7 min. hydrolys- able P)	Diffi- culty hydro- lysable P	Total P	Pyruvic acid	Change in inor- ganic P	Change in phospho- creatine-P	Change in pyro- phos- phate-P	Change in phospho- glyceric acid-P
A	2.16	0.064	0.144	0.560	0.176	3.04	1.54	+0.75	+0.064	+0.144	-1.24
B	1.41	0	0	0.192	0.112	1.71	—	—	—	—	—
C	1.47	0.048	0	0.512	0.736	2.72	Trace	+0.006	+0.048	0	-0.76
D	2.34	0	0	0.464	0.224	2.94	1.50	+0.93	0	0	-1.19

This experiment bears out the results of the last, but the phosphocreatine and pyrophosphate syntheses are much less and the production of inorganic phosphate much greater. In the light of the work described later, it seems likely that the enzyme responsible for the interaction between adenylypyrophosphate and creatine has been damaged by keeping, whilst the enzymes responsible for interaction between phosphoglyceric (or phosphopyruvic) acid and adenylic acid, and for the breakdown of adenylypyrophosphate to adenylic acid and orthophosphate, retain their activity. Creatine seems to have been dialysed away completely, but a trace of adenylic acid seems still to be present in C.

#### THE NATURE OF THE CO-ENZYME FUNCTION OF THE ADENYLIC COMPOUNDS.

The fact that creatine alone cannot bring about dephosphorylation of phosphoglyceric acid in muscle extract, while in presence of adenylic acid or adenylypyrophosphate as well such dephosphorylation occurs and phosphocreatine is produced, leads naturally to the idea that the adenylypyrophosphate added or formed from the adenylic acid phosphorylates creatine by a reverse Lohmann reaction. According to this view, the phosphate of the phosphoglyceric acid is transferred to adenylic acid and the inorganic P appearing as a final product of phosphoglyceric acid breakdown is due to the action of yet another enzyme which converts adenylypyrophosphate into adenylic acid and free phosphate. Lohmann and Meyerhof [1934] have stated that the formation of pyruvic acid from phosphoglyceric acid in extract needs adenylypyrophosphate as co-enzyme, adenylic acid working much less efficiently; they have also stated that phosphoglyceric acid breakdown has no effect in maintaining the adenylypyrophosphate concentration of an extract. Both these facts would militate against the view that the essential step in dephosphorylation of phosphoglyceric acid is the reaction with adenylic acid, giving adenylypyrophosphate. Our own experiments on these two points give opposite results, as is shown below, and Meyerhof and Lehmann also now take the view that adenylic acid reacts with phosphopyruvic acid, formed from the added phosphoglyceric acid. Barrenscheen and Beneschovsky [1935] too have shown that adenylic acid is as potent as adenylypyrophosphate in restoring the power of an extract to form pyruvic acid from phosphoglyceric acid.

*Exp. 5.* Frog muscle extract, kept 1 hour at room temperature, dialysed 4 hours. 10 ml. extract were made 0.04 *M* as regards bicarbonate and 0.004 *M* with regard to phosphate. 4 ml. of this extract were in each case diluted to 8 ml.; both solutions contained adenylypyrophosphate (0.96 mg. pyrophosphate-P) and 1.2 mg. Mg. A contained also 1.6 mg. phosphoglyceric acid-P. Both solutions were kept at room temperature, and samples were removed at 0, 5, 30 and 60 min. for the estimation of inorganic phosphate and pyrophosphate. The decrease in phosphoglyceric acid was calculated by subtracting the decrease in pyrophosphate from the increase in inorganic phosphate. (See Table IV.)

Table IV.

	Time min.	Inorganic P	Increase in inorganic P	Pyrophosphate-P	Decrease in pyrophosphate-P	Inorganic P from phosphoglyceric acid	Phosphoglyceric acid-P remaining
A	0	1.44	—	0.96	—	—	1.60
	5	1.97	0.53	0.89	0.07	0.46	1.14
	30	2.78	1.34	0.58	0.38	0.96	0.64
	60	3.50	2.06	0.17	0.79	1.27	0.33
B	0	1.44	—	0.96	—	—	—
	5	1.70	0.26	0.58	0.38	—	—
	30	2.08	0.64	0.13	0.83	—	—
	60	2.18	0.74	0.17	0.79	—	—

This experiment shows the effect which phosphoglyceric acid has in preventing the disappearance of adenylypyrophosphate. An attempt was now made to compare the activities of adenylypyrophosphate and adenylic acid as the co-enzyme of phosphoglyceric acid breakdown.

Fig. 1. ○—○ with adenylypyrophosphate; ●—● with adenylic acid.

*Exp. 6.* The alkaline extract was prepared exactly as in the last experiment. In each case 5 ml. of this solution were made up to 10 ml.; each solution contained 2 mg. phosphoglyceric acid-P and 1.5 mg. Mg. A contained 0.29 mg. pyrophosphate-P, and B an amount of adenylic acid equivalent to this adenylypyrophosphate. Both were kept at room temperature and samples were removed at 0, 5, 10, 20, 30, 60 min.; inorganic phosphate was estimated. (See Fig. 1.)

Fig. 1 shows that no difference in rate of breakdown of phosphoglyceric acid was observable in the two cases. The fact that the inorganic phosphate in A starts 0.24 mg. higher than in B suggests that the whole of the adenylypyrophosphate has been broken down to adenylic acid and orthophosphate in the first minute during mixing, before the first sample was taken, so that thereafter both samples were in the same situation with regard to co-enzyme.

In order to overcome this difficulty of rapid conversion of the adenylypyrophosphate into adenylic acid it was decided to use long-dialysed rabbit muscle extracts, as Lohmann [1934] has shown that such extracts lose their power to form inorganic phosphate from adenylypyrophosphate.

*Exp. 7.* Rabbit extract, kept 1 hour at room temperature, dialysed 15 hours at 0°. Two solutions were made up; 8 ml. of the extract were diluted to 16 ml., the final mixtures being 0.02 *M* with regard to bicarbonate and 0.002 *M* with regard to phosphate. Each solution contained 2.4 mg. phosphoglyceric acid-P and 2.4 mg. Mg. Solution A had adenylypyrophosphate (4.64 mg. pyrophosphate-P), and B an amount of adenylic acid equivalent to this adenylypyrophosphate. The solutions were kept at 28°, and samples were removed at 0, 5, 15, 30, 60 min. (See Table V.)

Table V.

Time min.	Inor- ganic P	Pyrophos- phate-P + inor- ganic P	Pyrophos- phate-P	Adenylic acid-P	Inorg. P after 2 hours' hydro- lysis	(2 hours' hydro- lysable P) - (7 min. hydro- lysable P)	Total P	Phospho- glyceric acid-P
A { 0	1.00	5.70	4.61	2.32	6.66	0.96	10.25	2.23
5	1.15	5.82	4.67	"	6.96	1.14	"	2.10
15	1.28	5.90	4.62	"	6.96	1.06	"	2.04
30	1.41	6.02	4.61	"	7.30	1.28	"	1.92
60	1.73	6.60	4.87	"	7.55	0.95	"	1.22
B { 0	1.41	3.08	1.67	1.96	3.97	0.89	6.01	0.97
5	1.47	3.90	2.43	"	4.60	0.70	"	0.15
15	1.57	3.90	2.33	"	4.60	0.70	"	0.15
30	1.83	3.97	2.15	"	4.80	0.83	"	0.08
60	2.59	4.16	1.57	"	4.73	0.57	"	0

In this experiment rapid interaction between adenylic acid and phosphoglyceric acid can be very clearly seen. About half the phosphoglyceric acid-P has disappeared before the first sample could be removed, and an amount of adenylypyrophosphate-P roughly equivalent has appeared. During the next 5 min. there is a further increase in adenylypyrophosphate-P and a decrease in phosphoglyceric acid-P. By the end of this time the phosphoglyceric acid is practically exhausted, and then disappearance of pyrophosphate with corresponding increase in inorganic phosphate begins. It is interesting to notice the differences in events in A. Here in the course of the whole hour less than half of the phosphoglyceric acid disappears. There is a slow steady increase in inorganic P, probably due to the slow breakdown of adenylypyrophosphate, the enzyme concerned not having been completely destroyed; but the adenylypyrophosphate concentration does not change, presumably being kept up by interaction of the adenylic acid formed with the phosphoglyceric (or phosphopyruvic) acid.

This experiment gives convincing proof of the reaction between adenylic acid and phosphoglyceric (or phosphopyruvic) acid, and shows the superiority of adenylic acid over adenylypyrophosphate in assisting the breakdown of phosphoglyceric acid. It is now necessary to consider the evidence for the reverse Lohmann reaction.

Meyerhof and Lohmann [1932] showed some years ago that in rabbit extracts at  $p_{\text{H}}$  9.0, which had been inactivated by standing 2 hours at room temperature, a synthesis of phosphocreatine took place when adenylypyrophosphate was added, and the increase in phosphocreatine was equivalent to the pyrophosphate disappearance. It is now necessary, however, to show that this reverse reaction can go on under the conditions used in the experiments just described, *i.e.* with dialysed extracts and at  $p_{\text{H}}$  7.2.

*Exp. 8.* Frog muscle extract was used; it was kept 1 hour at room temperature and was dialysed 4 hours at 0°. 7 ml. were made up to 14 ml.; the solution was made 0.02 *M* with regard to bicarbonate and 0.004 *M* with regard to phosphate. 25 mg. of creatine were added and adenylypyrophosphate (4.4 mg. pyrophosphate-P). It was kept at room temperature for 1 hour and samples were removed at 0, 2, 15, 30 and 60 min. (See Table VI.)

Table VI.

Time min.	Phospho-creatine-P	Inorganic P	Pyrophosphate-P + inorganic P	Pyrophosphate-P	Decrease in pyrophosphate-P	Increase in phosphocreatine-P	Increase in phosphocreatine-P + inorganic P
0	—	3.36	7.05	3.69	—	—	—
2	0.294	3.70	7.05	3.35	0.34	0.294	0.634
15	0.672	4.60	7.12	2.52	1.17	0.672	1.912
30	0.658	5.60	6.89	1.29	2.40	0.658	2.898
60	Trace	6.72	7.00	0.28	3.41	0	3.360

With this dialysed extract the observable synthetic activity is very small; the breakdown of adenylypyrophosphate to adenylic acid and free phosphate goes on very rapidly and the adenylic acid thus formed must react with the phosphocreatine synthesised. The phosphocreatine concentration reaches a maximum in about 30 min., after which the concentration of adenylic acid has become high enough to cause its complete disappearance.

The experiment was repeated with frog muscle extract which had been dialysed 16 hours (after standing 1 hour), as this treatment was shown by Lohmann [1934] to damage or destroy the enzyme responsible for adenylypyrophosphate breakdown, while not greatly affecting the enzyme responsible for reaction between adenylic acid and phosphocreatine.

*Exp. 9.* The solutions were made up exactly as in the last experiment, but no phosphate was added, in order that changes in pyrophosphate-P and phosphocreatine-P might show up better. No calcium precipitation was performed, but the phosphocreatine was estimated by the extrapolation method of Eggleton and Eggleton [1927], and the pyrophosphate was determined by finding the increase after 7 minutes' hydrolysis in the trichloroacetic acid extract, instead of in the solution of the calcium precipitate as usual. Special precautions were taken to keep the samples very cold,  $-12^{\circ}$ , until the estimations could be carried through; the protein precipitation was carried out by adding the trichloroacetic acid to the frozen samples just before each extrapolation was done and thawing rapidly. Samples were taken at 0, 15, 30, 60, 90 and 120 min. (See Table VII and Fig. 2.)

In these experiments the increase in inorganic phosphate is much slower, although not entirely inhibited. During the first 30 min., however, 75% of the pyrophosphate-P disappearing is transferred to creatine. The phosphocreatine concentration reaches a maximum after about an hour; it then falls off, as the concentration of adenylic acid increases. If the breakdown of adenylypyrophosphate to adenylic acid and free phosphate had been entirely inhibited,

no doubt an equilibrium would have been reached at some definite concentration of the reactants, as in Lohmann's experiment starting with phosphocreatine and adenylic acid.

Table VII.

Time min.	Phospho-creatine-P + inorganic P	Inorganic P	Phospho-creatine-P	Inorg. P after 7 min. hydrolysis	Pyrophosphate-P	Decrease in pyrophosphate-P	Increase in phospho-creatine-P + inorganic P

### DISCUSSION.

From the work of Meyerhof's school it seems likely that the co-enzyme is only necessary during glycogen breakdown to lactic acid at the stages where a change in phosphorylation takes place. It has been shown to be unnecessary in: (a) The change from hexosediphosphate to triosephosphate [Meyerhof and Lohmann, 1934]. (b) The change from phosphoglyceric acid to phosphopyruvic acid [Lohmann and Meyerhof, 1934]. (c) The interaction of pyruvic acid with glycerophosphate to give one equivalent of lactic acid with no setting free of phosphate [Meyerhof and Kiessling, 1933, 2]. There seem to be no data as to the necessity of co-enzyme for the dismutation of triosephosphate into phosphoglyceric acid and glycerophosphate. The remaining stages, at which co-enzyme is necessary are: (a) The phosphorylation of carbohydrate. (b) The dephosphorylation of phosphopyruvic acid. Evidence is provided in this paper for the co-enzyme function of adenylic acid as a phosphate acceptor in the formation of pyruvic acid from phosphopyruvic acid.

That not adenylic acid, but adenylypyrophosphate, is necessary as a phosphate donor at the first stage is indicated by many earlier experiments in which, for the production of lactic acid from glycogen, adenylypyrophosphate is

much more efficient than adenylic acid [*cf.* Lohmann, 1931, 2]. We may quote here one experiment of our own in which frog muscle extract, inactivated by standing 1 hour and dialysed 3 hours, showed no power of esterification of glycogen or lactic acid production when adenylic acid was added but regained both activities to some extent when adenylypyrophosphate was added.

The synthesis of 1 g. molecule of adenylypyrophosphate from 1 of adenylic acid and 2 of free phosphate requires energy to the value of 25,000 cal. Hydrolysis of 2 g. molecules of phosphopyruvic acid provides only 16,000 cal. [Meyerhof and Lehmann, 1935]. It seems then, that synthesis of adenylypyrophosphate at the expense of phosphopyruvic acid breakdown must be an endothermic reaction. Nevertheless, as shown in Exp. 7, the reaction appears to go to completion, for the phosphoglyceric acid disappeared completely while adenylypyrophosphate was still present.

The reversibility of the Lohmann reaction seems to be established, not only from our own experiments described here, but also from experiments of Meyerhof and Lehmann not yet published in full. In this connection the work of Lohmann [1935] on the presence of both adenylypyrophosphate and adenosinediphosphate in heart and smooth muscle is of great interest. To suppose a direct reaction according to the equation:

would involve the very unlikely assumption of a trimolecular reaction in each direction. It seems more reasonable to suggest that the reaction goes in two stages, first with production of adenosinediphosphate, which then reacts with a second molecule of creatine or phosphocreatine. The reaction between adenosinediphosphate and phosphoarginine has been demonstrated by Lohmann in crab muscle. In heart and smooth muscle the change from the triphosphate to the diphosphate is very rapid, making the triphosphate difficult to isolate. It may be that in skeletal muscle it is the diphosphate which is unstable and so has escaped detection.

Finally, we should like to discuss an important deduction which has been drawn by Parnas and his co-workers [1935, 2; Mann, 1935] from certain of their experiments. They found: (a) That, whilst in a "brei" made with water ammonia formation takes place very rapidly, in a "brei" made with *M/10* phosphate solution this ammonia formation may be inhibited for 30–60 min. (b) This phosphate inhibition of ammonia production disappears if fluoride or iodoacetic acid is added to the "brei". (c) In a phosphate "brei" with fluoride, the ammonia inhibition takes place if phosphoglyceric or pyruvic acid is added, whilst in a phosphate "brei" with iodoacetic acid, the ammonia inhibition only takes place if phosphoglyceric acid is added, pyruvic acid having no effect. The conclusion was drawn that a substance intermediate between pyruvic acid and phosphoglyceric acid, *i.e.* phosphopyruvic acid, performs the phosphorylation of adenylic acid or creatine, and further, that this phosphopyruvic acid can be synthesised by the "brei" from pyruvic acid (whether added to or formed in the muscle) and free phosphate, if the phosphate concentration is high enough. This last reaction, if correct, is very interesting; it is endothermic, and the question of the energy provision arises; also it is unusual amongst all the reactions we have been considering, in involving the esterification of free phosphate. It seems to us, however, that the evidence so far brought forward is hardly conclusive. In the case of the phosphate alone, the evidence is not very convincing that the effect is not due simply to a more favourable milieu for prolonged carbohydrate breakdown. It seemed possible, also, that a high inorganic

phosphate concentration might slow the formation of adenylic acid and free phosphate from adenylypyrophosphate. This turned out not to be the case, however. When adenylypyrophosphate was added to a muscle extract (after standing 1 hour at room temperature and 2 hours' dialysis at 0°) the formation of free phosphate from it went on even more rapidly in presence of 0.05 *M* phosphate than in absence of any added phosphate.

In the case of the pyruvic acid effect in fluoride "brei" it seems at present difficult to exclude the possibility that this is due to its interaction with glycerophosphate already in the muscle leading to the formation of an equivalent amount of triosephosphate and ultimately to phosphoglyceric acid. If added phosphoglyceric acid can have the inhibitory effect on  $\text{NH}_3$  formation, as in Parnas's experiments, then it seems that pyruvic acid must have this effect also, since fluoride does not prevent formation of glycerophosphate or reaction between pyruvic acid and glycerophosphate. That phosphoglyceric acid can inhibit means that the fluoride poisoning (which prevents the change of phosphoglyceric acid into phosphopyruvic acid [Embden and Deuticke, 1934; Lohmann and Meyerhof, 1934]) is incomplete, or else that phosphoglyceric acid itself can phosphorylate adenylic acid. The fact that pyruvic acid has no effect in iodoacetate "brei" is easily understood on these lines, as iodoacetate, besides preventing formation of phosphoglyceric acid, also prevents the reaction together of pyruvic acid and glycerophosphate [Embden and Deuticke, 1934; Meyerhof and Kiessling, 1933, 2]. There seems no reason why it should inhibit synthesis of phosphopyruvic acid if this were going on, as it does not inhibit dephosphorylation of phosphopyruvic acid.

Light has thus been shed by much recent work on the rôle of the adenylic component of the co-enzyme system; the part played by magnesium, however, remains completely obscure. Another obscure question is the mode of entry of inorganic P into the cycle of reactions. This may not occur to any great extent *in vivo*, but *in vitro* it certainly does; for instance in normal glycolysis in muscle extract with the complete co-enzyme system present a mixture of hexosediphosphate and hexosemonophosphate temporarily accumulates. Without co-enzyme a small amount of esterification goes on [Lohmann, 1931, 3], leading to formation of some difficultly hydrolysable hexose esters, and in presence of fluoride or iodoacetic acid too, carbohydrate is esterified. As we have seen, the esterification of pyruvate remains problematical, and the interaction with free phosphate seems chiefly to concern the hexose stage.

*Note.* Just as this paper was ready for the press, the detailed account of the experiments of Ostern *et al.* [1935, 2] appeared, together with a theoretical discussion by Parnas and Ostern [1935].

#### SUMMARY.

1. Using dialysed muscle extracts, it has been shown that, in presence of adenylic acid and magnesium, added creatine can be converted into phosphocreatine during the breakdown of phosphoglyceric acid.

2. The two reactions involved in this synthesis have been demonstrated: (a) The reaction between phosphoglyceric acid (or phosphopyruvic acid) and adenylic acid to form adenylypyrophosphate and pyruvic acid. (b) The reaction between adenylypyrophosphate and creatine to form phosphocreatine and adenylic acid.

3. Evidence is brought forward for the view that the co-enzyme function of the adenylic acid and adenylypyrophosphate in muscle glycolysis consists in their ability to act respectively as phosphate acceptor and phosphate donator.

# CCXLI. THE EFFECT OF FEEDING CACAO SHELL TO COWS ON THE VITAMIN D CONTENT OF BUTTER (MILK).

BY STANISŁAW KAZIMIERZ KON AND KATHLEEN MARY HENRY.

*From the National Institute for Research in Dairying, University of Reading.*

*(Received July 24th, 1935.)*

It has recently been reported by Knapp and Coward [1934] that cacao shell, an important by-product of chocolate manufacture, is rich in vitamin D. The sample examined by them contained 28 International Units (I.U.) per g. and was therefore about one-quarter as potent as an average cod-liver oil. For a vegetable product the potency is quite exceptional.

As cacao shell is mainly used in cattle food, feeding tests with milch cows have been carried out at this Institute in collaboration with Mr A. W. Knapp and Mr A. Churchman of Messrs Cadbury Bros., Ltd., of Bournville and it is proposed to present here the results of vitamin D assays carried out on butters from cows which received cacao shell in their rations and on butters from control animals.

## EXPERIMENTAL.

### *Estimation of the vitamin D potency of the cacao shell used in feeding experiments.*

As a preliminary to the experiment proper the vitamin D content of the sample of cacao shell used in the cow feeding experiments was estimated in curative and protective experiments on rats. The cacao shell was part of a half-ton sample of the commercial product sent to us by Messrs Cadbury Bros., Ltd. This was a carefully taken sample representative of a bulk of 3467 cwt. of shell. For the rat tests the shell was ground to a fine powder.

(a) *Curative test.* Young rats were weaned when weighing about 60 g. and were placed on the 2965 diet of Steenbock for from 3 to 3½ weeks until definitely rachitic. They were then given in one single dose at the beginning of the 10-day test either cacao shell or the international standard for vitamin D (v.D. 9). Of the latter, two levels, 2 and 5 units, were given. The corresponding levels of cacao shell were calculated on the basis of the value given by Knapp and Coward [1934], namely 28 I.U. per g. For feeding the finely ground cacao shell was mixed with a little castor sugar and water and offered in palette dishes in quantities of 71 mg. and 179 mg. (respectively equivalent on the above basis to 2 and 5 I.U. of vitamin D). The consumption was complete in all cases. After 10 days the rats were killed by coal gas and the wrist bones were placed in 4% formaldehyde for several days. They were then split longitudinally, placed in palette dishes containing a 1.5% solution of silver nitrate and exposed to light. The degree of healing was then estimated by comparing the deposition of calcium salts in the bones with the graded scale in use in this Institute for assessment of extent of healing. The results are given in Table I.

In the course of the last few years numerous estimations of the healing effect of graded doses of the international standard for vitamin D have been

Table I. *The vitamin D content of cacao shell.*

Curative experiments.									
Dose	Rat	Litter	Score		Dose	Rat	Litter	Score	
			Indi- vidual	Av.				Indi- vidual	Av.
2 units inter- national standard	4336	1	2.0		5 units inter- national standard	4340	1	2.0	
	4350	2	1.5			4346	2	0.5	
	4354	3	0.5			4358	3	1.5	
	4372	4	0.5	1.1		4368	4	5.5	
						4377	5	1.0	2.1
71 mg. cacao shell	4337	1	2.25		179 mg. cacao shell	4341	1	2.25	
	4351	2	1.00			4347	2	2.0	
	4355	3	0.50			4359	3	3.5	
	4373	4	2.00	1.4		4369	4	3.5	2.8

carried out in this laboratory. From the results the following equation relating the degree of healing (score) expressed in arbitrary units to the dose has been constructed [Kon]:

$$\text{Score (arbitrary units)} = 4.22 + 3.79 \log \text{dose (I.U.)}.$$

By calculating from this equation it is found that the ratio of scores  $\frac{1.4}{1.1}$  obtained for the lower level of cacao shell and 2 units of international standard for vitamin D respectively corresponds to a ratio of dosages  $\frac{0.18}{0.15}$ . Therefore 71 mg. of cacao shell contain  $\frac{0.18}{0.15} \times 2 = 2.4$  I.U. and 1 g. of cacao shell  $\frac{2.4 \times 1000}{71} = 34$  I.U. of vitamin D.

A similar calculation for the higher levels of shell and international standard shows that the ratio of scores  $\frac{2.8}{2.1}$  corresponds to a ratio of dosages  $\frac{0.42}{0.28}$  and that 179 mg. of cacao shell contain 7.5 I.U. Hence 1 g. of cacao shell contains  $\frac{7.5 \times 1000}{179} = 42$  I.U. of vitamin D.

Taking an average of the two values the curative test gives a content of 38 I.U. of vitamin D per g. of cacao shell.

(b) *Protective test.* In this test the vitamin D contents of cacao shell and of cacao shell fat were measured in terms of the international standard for vitamin D. Young rats were weaned when weighing about 60 g. and were placed on the 2965 diet of Steenbock. The various addenda were given from the start daily for 5 weeks with the exception of Sundays. Finely ground cacao shell was diluted 10 times with icing sugar and given at 2 levels of intake, namely 6.7 mg. and 13.4 mg. daily (equivalent to 0.187 and 0.375 I.U. respectively on the assumption that 1 g. of cacao shell contains 28 units).

A sample of cacao shell fat extracted in the laboratory of Messrs Cadbury was also tested. Two levels, 0.62 mg. and 1.24 mg. were fed dissolved in olive oil. The cacao shell contained, according to an analysis carried out by Messrs Cadbury, 4.6% fat. On this basis and assuming that the whole of the antirachitic potency of cacao shell is present in the fat the above levels were equivalent to 0.375 and 0.75 I.U. of vitamin D. The international standard for vitamin D (v.d. 9) was fed at a single level of 0.41 unit. In addition one group of rats was given no supplement to the rachitogenic diet and served as negative control.

At the end of 5 weeks the rats were killed by coal gas, their femora and humeri after cleaning were defatted by extraction with several changes of alcohol for

72 hours in a Soxhlet extractor, dried and ashed at 700° in an electric furnace. For each rat a duplicate determination on one femur and humerus was carried out (Table II).

Table II. *The vitamin D content of cacao shell and of cacao shell fat.*

Protective experiments.									
Dose	Rat	Litter	Ash %		Dose	Rat	Litter	Ash %	
			Indi- vidual	Av.				Indi- vidual	Av.
Cacao shell 6.7 mg.	4419	8	43.3		Cacao shell 13.4 mg.	4443	7	51.5	
	4450	4	43.3			4430	5	46.7	
	4459	3	41.9			4455	3	46.0	
	4470	1	42.0	42.6		4465	2	49.0	48.3
Cacao shell fat 0.62 mg.	4416	8	42.9		Cacao shell fat 1.24 mg.	4444	7	45.0	
	4449	4	34.8			4432	6	49.8	
	4460	3	39.3			4456	3	48.2	
	4474	1	45.1	40.5		4466	2	50.3	48.3
Standard 0.41 I.U.	4420	8	41.9		Negative con- trols	4440	9	29.1	
	4431	6	46.5			4435	6	26.7	
	4462	2	50.5			4469	2	26.7	
	4473	1	51.7	47.6		4477	1	26.2	27.2

The gains in percentage of ash over the negative controls were as follows:

Cacao shell	6.7 mg. level	+15.4
Cacao shell	13.4 "	+21.1
Cacao shell fat	0.62 "	+13.3
Cacao shell fat	1.24 "	+21.1
International standard 0.41 unit level		+20.4

In the same way as for curative tests the following equation relating the degree of protection to the dose has been worked out for protective experiments:

$$\text{Gain in ash \%} = 26.33 + 16.6 \log \text{dose (I.U.) [Kon].}$$

Calculations similar to those described above in the case of curative tests show that the ratio of gains in ash percentage  $\frac{15.4}{20.4}$  given by the 6.7 mg. level of cacao shell and the standard is equivalent to a dose ratio of  $\frac{0.22}{0.44}$  and that 6.7 mg. of cacao shell contain 0.205 I.U. and 1 g. of cacao shell = 31 I.U. of vitamin D.

For the higher level of cacao shell the ratio of doses works out at  $\frac{0.48}{0.44}$  and 13.4 mg. of cacao shell contain 0.45 I.U. From this 1 g. of cacao shell contains 34 I.U.

Taking an average of the two figures, a value of 32.5 I.U. of vitamin D per g. of cacao shell is obtained from protective tests and as the average of the curative tests worked out at 38 units, a value of 35 I.U. of vitamin D per g. of cacao shell may be accepted as the result of all the tests carried out in this Institute. We have been informed by Messrs Cadbury that a sample of the same consignment of cacao shell as sent to this Institute was submitted to Dr K. H. Coward at the laboratories of the Pharmaceutical Society of Great Britain and that she reported for it a value of 28 I.U. of vitamin D per g., identical with that previously published by Knapp and Coward [1934]. Our value is slightly higher than that obtained by Dr Coward but, in view of the small number of animals used by us, the agreement is very satisfactory.

The calculations for the cacao shell fat give the following results:

*Lower level of cacao shell fat.* Ratio of doses  $\frac{0.164}{0.44}$ . Hence 0.62 mg. of fat contains 0.153 I.U. and 1 g. contains 247 I.U. of vitamin D.

*Higher level of cacao shell fat.* Ratio of doses  $\frac{0.48}{0.44}$ . Therefore 1.24 mg. of fat contain 0.45 I.U. and 1 g. contains 367 I.U. of vitamin D.

The agreement is not very good but differences of this magnitude are to be expected when relatively small numbers of animals are used. By averaging the above two values a figure of 307 I.U. per g. of cacao shell fat is obtained. This is about three times the vitamin D content of an average cod-liver oil. From this value and from the fat content of cacao shell it may be calculated that the extractable fat carries about 40 % of the total activity of cacao shell.

*The feeding of cacao shell to cows and the estimation of its effect on the vitamin D content of butter (milk).*

The feeding of the cacao shell was carried out during the winter stall feeding period of 1935. Four Shorthorn cows were used for this experiment. They were kept in the same cow-byre and were not allowed out to grass. From January 8th, 1935, all four cows received the following mixture of concentrates:

3 parts dried grains,  
2 parts maize germ cake,  
1 part soya bean meal.

In addition each cow was given daily:

2 lb. of hominy chop,  
7 lb. of hay,  
45 lb. of mangels.

The cows were kept on this ration till February 8th, 1935. The milks yielded by each cow between the evening milking on February 5th and the morning milking on February 8th (both dates inclusive) were separated and butters were churned from the unpasteurised and unripened creams. The butters were melted at 50°, filtered and the butter fats stored at -2° until required for tests. On February 8th two cows were given  $\frac{1}{2}$  lb. of cacao shell, this was increased to 1 lb. on February 9th, 1½ lb. on February 12th and on February 13th to 2 lb., fed invariably in the coarse flaky form in which it occurs in commerce. The feeding of cacao shell was continued at this level until March 17th. The cacao shell was taken into consideration when calculating the amount of concentrates fed daily to each cow according to her milk yield as is usual in our dairy herd. The remaining two cows were kept on the original ration throughout the experiment. Butters were churned again as described above from milks collected between the evening milking on March 10th and the morning milking on March 13th (both dates inclusive), that is after the experimental cows had received 2 lb. of cacao shell daily for 4 weeks. In this way eight samples of butter fat were obtained. Aliquots of each two samples representing one treatment were then pooled, the blending being done on the basis of the fat yields of the cows. The four samples so obtained, representing the four treatments (control cows—pre-experimental and experimental periods, "cacao shell cows"—pre-experimental and experimental periods), were then tested in protective experiments on rats at one level of intake, 0.3 g. of butter fat per rat per day (with the exception of Sundays), and compared with three levels of the international standard for vitamin D with the following results.

Table III. *The vitamin D content of butter from cows receiving cacao shell in their diet and of butter from control cows.*

	4703	9	40.8	42.6		4754	10	26.3	
						4755	10	28.9	
						4604	12	31.3	29.2

The gains in percentage of ash over negative controls were as follows:

"Cacao shell" butter	Pre-experimental	+ 1.0
	Experimental	+ 11.5
Control butter	Pre-experimental	+ 2.3
	Experimental	+ 2.4
International standard for vitamin D (v.D. 10)	0.05 unit	+ 0.8
	0.10 unit	+ 8.5
	0.20 unit	+ 13.4

For the calculation of the ratio of dosages the response given by 0.05 unit of standard was used for the low potency butters whilst that given by 0.2 unit of standard was used for the experimental "cacao shell" butter. The calculations were carried out in the same way as described in the earlier part of this paper and the following values were obtained:

"Cacao shell" butter fat	Pre-experimental 1 g. contains 0.17 I.U. of vitamin D
	Experimental 1 g. contains 0.51 I.U. of vitamin D
Control butter fat	Pre-experimental 1 g. contains 0.20 I.U. of vitamin D
	Experimental 1 g. contains 0.21 I.U. of vitamin D

If the "cacao shell" butter is compared with the control butter then the feeding of cacao shell has resulted in an increase in potency of  $\frac{0.51}{0.21}$  = approx. 2.5 times.

When comparing the butters yielded by the same cows before and after the feeding of cacao shell the increase is  $\frac{0.51}{0.17} = 3$  times. In our experience and under our conditions winter Shorthorn butter fat contains about 0.20–0.25 I.U. of vitamin D per g., summer butter fat 0.50–0.60 [Kon]. It may be said therefore that the feeding of 2 lb. daily for a month of cacao shell, equivalent to about 32,000 I.U. of vitamin D daily, to cows on a winter ration has resulted in raising the vitamin D content of their butter fat (and therefore of their milk) from the winter to the summer level.

#### SUMMARY.

1. Cacao shell, a by-product of chocolate manufacture, was found in curative and protective experiments on rats to contain 35 I.U. of vitamin D per g., in good agreement with the findings of Knapp and Coward [1934] who reported for the product a content of 28 units per g.

2. Cacao shell fat contains about 300 I.U. of vitamin D per g. The extractable fat carries about 40 % of the total activity of the cacao shell.

3. The feeding to two Shorthorn cows under winter stall feeding conditions of 2 lb. of cacao shell daily for a month (equivalent to 32,000 I.U. of vitamin D daily) has resulted in increasing the vitamin D content of their butter fat (and milk) from the winter to the summer level.

The above report deals only with one aspect of the investigation of cacao shell as a food for cows. The effect of the cacao shell feeding on the health of the cows, the milk yield, fat percentage, solids-not-fat *etc.* has been investigated by Capt. J. Golding and other members of the staff of N.I.R.D. The results will be published in detail elsewhere. But it may be stated here that no untoward effects whatever have been noted in the present experiment.

Our thanks are due to Messrs Cadbury Bros., Ltd., Bournville whose collaboration and support has made this investigation possible. We are indebted to Miss D. V. Dearden for the churning of the butters and to Miss M. Chapman for help with the rats.

# CCXLII. THE NATURE OF THE "SPOROGENES VITAMIN", AN ESSENTIAL GROWTH FACTOR FOR *CL. SPOROGENES* AND RELATED ORGANISMS.

BY ALWIN MAX PAPPENHEIMER, JUN.<sup>1</sup>

*From the National Institute for Medical Research, London, N.W. 3.*

*(Received July 24th, 1935.)*

IN a series of papers on the nutritional requirements of bacteria [Knight and Fildes, 1933; Fildes, 1935; Fildes and Richardson, 1935] it has been shown that *Cl. sporogenes* and certain other obligate anaerobes may be grown on media containing salts and known amino-acids only when a trace of an unknown ether-soluble acid, which has been called the "sporogenes vitamin", is present.

The present paper gives a further study of the chemical properties of this essential growth factor, carried out in collaboration with Dr Fildes and Mr Knight at the Middlesex Hospital. Although we are unable to report the successful isolation of the "vitamin" in crystalline form, we have succeeded in effecting substantial purification and have obtained preparations of constant composition and properties and of uniformly high activity in promoting growth on otherwise deficient media.

## EXPERIMENTAL.

### *Biological testing.*

The tests on the activity of various preparations containing the sporogenes growth factor were carried out in the Department of Bacterial Chemistry, Middlesex Hospital. Fivefold dilutions of the solution to be tested were added to a series of tubes containing the deficient medium, which were then inoculated with a standard suspension of *Cl. sporogenes* spores. The deficient medium used for most of the testing was an acid hydrolysate of gelatin with the addition of 0.02 % tryptophan, 0.2 % thiolacetic acid *plus* the requisite salts [Knight and Fildes, 1933]. Later tests were made using a medium containing only amino-acids, most of which were synthetic, *plus* thiolacetic acid and the necessary salts [Fildes and Richardson, 1935]. Results with the latter medium were more clear cut and must be regarded as more significant. The reason for this appears to be that the gelatin contains traces of substance having the biological activity in question, but in inactive form, not activated by acid hydrolysis but possibly activated by bacterial growth. These traces sometimes permit very slight growth which does not increase. This does not occur with the amino-acid medium.

### *Materials.*

Initial attempts to isolate the essential growth factor were carried out with a commercially prepared fraction from pregnant women's urine. An oil was obtained which was active in concentrations of 0.01  $\gamma$  per ml. in promoting growth on the gelatin hydrolysate medium. As will become apparent from evidence given later, this corresponds to an activity of about 0.1  $\gamma$  per ml. on the amino-acid medium. Unfortunately this product quickly lost its activity on

<sup>1</sup> National Research Council Fellow in Medicine, 1933-34.

standing, before much could be learned of its properties. Subsequent preparations have all been kept as the methyl ester, which shows no diminution in activity after long standing in the cold.

Since no further supply of this urine concentrate was available, we next attempted to isolate the factor from yeast. A laborious fractionation of 120 kg. of brewer's yeast yielded about 0.5 g. of impure methyl ester of the active substance, which could not be distilled without destruction. The great instability of the yeast preparations suggests that the growth-promoting activity may be due to a different substance from that in urine.

It therefore became necessary to search for a new source of material. Tests on fresh human urine showed that the commercial concentrate which we had previously used only contained about 1% of the active factor present in the original fresh urine. Further, the urine of two herbivorous animals (horse and cow) was found to be about ten times more active in promoting the growth of *Cl. sporogenes* than the fresh urine of man. Through the courtesy of Dr A. Girard of Paris we were able to test some by-products from the commercial preparation of oestrogenic hormones from pregnant mare's urine. These were found to be highly active. To our surprise, we found that the active factor had been completely extracted from a 50% pyridine-ether solution of the saponifiable *plus* non-saponifiable material of mare's urine by concentrated hydrochloric acid. Accordingly, Dr Girard, to whom we wish to express our sincere thanks, kindly sent us 10 litres of this highly active solution, containing the growth factor from 1300 litres of mare's urine, and this was used in the work to be described.

#### *Method of separation.*

Table I shows the steps followed in separating the sporogenes growth factor from the mare's urine concentrate. Activity at each stage was followed by

Table I. *Preparation of sporogenes growth factor from mare's urine.*

(1) 10 l. mare's urine concentrate (contains HCl, pyridine). Make alkaline to litmus with solid $\text{Na}_2\text{CO}_3$ (7 kg.). Steam distil.	— distillate
	Residue 15 l. (active)
(2) Concentrate <i>in vacuo</i> to 2.5 l., acidify to Congo red with $\text{H}_2\text{SO}_4$ and continuously extract with ether (24 hours)	— acid aqueous residue
	Ether extract 1000 ml. (active)
(3) Concentrate ether extract to 200 ml. and precipitate with 400 ml. light petroleum	— supernatant
	Precipitate 25 g. (active)
(4) Esterify with 3% $\text{HCl}-\text{CH}_3\text{OH}$ . Extract ether solution of esters with $\text{NaHCO}_3$ and $\text{NaOH}$	— $\text{NaHCO}_3$ and $\text{NaOH}$ fractions
	Ether residue (active on hydrolysis) (Methyl esters)
(5) High vacuum distillation	— Fraction distilling below $90^\circ$ (inactive)
	Middle fraction $90-100^\circ$ (active on hydrolysis)
(6) Redistillation	7 g. purified methyl ester: activity on hydrolysis 0.04 $\gamma$ /ml.

determining the minimum amount of material necessary to add to 1 ml. of deficient medium, in order to produce just visible growth in twenty-four hours.

*Step 1.* After steam-distillation, a considerable amount of tar was removed by filtration.

*Step 2.* During concentration of the filtrate the salt which separated was removed from time to time by filtration. After acidifying the concentrate and filtering off precipitated tar the filtrate was coloured light orange. Peroxide-free ether was used for the subsequent extraction and throughout this work.

*Step 3.* The oil precipitated with light petroleum was dissolved in 150 ml. water and kept in the cold as a stock solution.

*Step 4.* 30 ml. of this solution were extracted ten times with a total of 500 ml. of ether and the extract was dried over  $\text{Na}_2\text{SO}_4$ . After removing the ether, the residue was refluxed for one hour with 50 ml. 3%  $\text{HCl}-\text{CH}_3\text{OH}$ . The alcohol was removed *in vacuo*, and the residue, dissolved in ether, shaken out twice with 5%  $\text{NaHCO}_3$ , twice with 0.5%  $\text{NaOH}$ , and finally with dilute  $(\text{NH}_4)_2\text{SO}_4$  solution.

*Steps 5-6.* The residual esters, freed from phenolic substances, were then distilled in a high vacuum (*ca.* 0.001 mm. Hg). The first fraction (0.87 g.) coming over below  $90^\circ$  was inactive on hydrolysis and was discarded. The middle fraction ( $90-100^\circ$ ) contained practically the entire activity (after hydrolysis) and weighed 2.2 g. 0.3 g. dark residue remained in the distilling flask. The middle fraction was then redistilled and the fraction coming over between  $94^\circ$  and  $96^\circ$  collected. The yield of pale yellow oil was 1.53 g., 0.001-0.005% of which was sufficient to activate 1 ml. of gelatin hydrolysate medium after alkaline hydrolysis. The activity on the amino-acid medium was somewhat less (0.04%/ml.) but the titration was far more reproducible. The total yield of redistilled esters from 10 litres of mare's urine concentrate was about 7 g.

#### *Properties of distillate.*

The methyl ester failed to crystallise even when kept at the temperature of solid  $\text{CO}_2$  for two days. The oil was very soluble in ether, alcohol and benzene, slightly soluble in water, but insoluble in light petroleum. Millon,  $\text{SbCl}_3$  and Liebermann-Burchard reactions were negative. With *p*-dimethylaminobenzaldehyde a violet-pink colour of moderate intensity was obtained on addition of excess concentrated  $\text{HCl}$ . A burnt orange colour was produced on a pine splint moistened with  $\text{HCl}$ . The oil contains no nitrogen or sulphur. It has no appreciable optical rotation in 4% solution.

*Analysis of methyl ester.* Three independent distillates gave the following analyses. (Found C, 62.65, 62.43, 62.51; H, 7.00<sup>1</sup>, 6.87<sup>1</sup>, 6.77%. Calculated for  $\text{C}_{11}\text{H}_{14}\text{O}_4$ , C, 62.85; H, 6.67; Calculated for  $\text{C}_{11}\text{H}_{16}\text{O}_4$ , C, 62.26; H, 7.55%.)

Mol. wt. by freezing point of benzene, mean value found, 209; calculated for  $\text{C}_{11}\text{H}_{14}\text{O}_4$ , 210.

*Hydrolysis of methyl ester.* The methyl ester itself is only 1/25 as active as the free acid. This slight activity is probably due to partial hydrolysis in the culture medium during test.

268 mg. of ester were refluxed for one hour with 5 ml. of *N*  $\text{NaOH}$ . The solution was saturated with  $\text{CO}_2$ , extracted twice with ether and finally acidified with dilute sulphuric acid and thoroughly extracted with peroxide-free ether. After drying the ether extract over  $\text{Na}_2\text{SO}_4$  and removing the ether, 240 mg. of

<sup>1</sup> For the first and second analyses we are indebted to Mr A. W. Spratt; the third was made by Roth (Heidelberg).

yellow oil remained which rapidly darkened on standing in air or in a vacuum desiccator.

The free acid was very soluble in alcohol and ether, moderately soluble in cold water and benzene, but insoluble in light petroleum and cyclohexane. The acid gave no colour with Millon's reagent or with ferric chloride. Permanganate was readily reduced in both acid and alkaline solutions in the cold, and the silver mirror test with Tollen's reagent was positive on heating. Neither the free acid nor its methyl ester gave any colour reactions for aldehydes on oxidation with lead tetra-acetate [Criegee, 1931], nor could any ketone be detected. The acid retained its full activity after treatment with boiling *N* HCl or *N* NaOH for three hours, but was destroyed by treatment with norite charcoal at 100°.

**Titration of free acid.** Duplicate determinations of the acid equivalent of the freshly prepared free acid gave values of 206 and 209. A monobasic acid,  $C_{10}H_{12}O_4$ , requires an acid equivalent of 196. One of the above titrations was done electrometrically using the glass electrode<sup>1</sup>. The points agree well with the theoretical curve for a single substance with  $p_K' = 4.7$  (Fig. 1).

Fig. 1. Titration curve of a highly active "sporogenes vitamin" preparation. Crosses represent back-titration with 0.1N HCl.

**Attempts to obtain a crystalline derivative of the active factor.** All attempts to crystallise the acid and its methyl ester and to prepare crystalline derivatives have met with failure. The ester reacts with hydrazine and phenylhydrazine to form acid hydrazides and with ammonia to form the amide. From these derivatives the active free acid can be quantitatively regenerated by alkaline hydrolysis. It can be esterified with 3:5-dinitrobenzoyl chloride in pyridine and other reagents which generally yield crystalline derivatives with hydroxy-compounds. Although reaction takes place and products are obtained with entirely different

<sup>1</sup> We are indebted to Dr W. J. Elford for the use of the glass electrode.

solubilities, all have been oils. Benzoyl- and tolylsulphonyl-derivatives have been prepared from the free acid by the Schotten-Baumann reaction. However, benzoylation and acylation of the free acid in dry solvents such as pyridine yield only tars and the active principle is destroyed. We have also prepared strychnine, brucine and other alkaloidal salts from the acid, all of which resist attempts to crystallise them. Even the *p*-phenylphenacyl derivative fails to crystallise. Lead, zinc and barium salts are hygroscopic and form resins on drying.

*Bromine titration of methyl ester.* 47.9 mg. of oil required 9.54 ml. of 0.1 *N* bromine [Reindel and Niederländer, 1929]. On addition of 1%  $\text{KIO}_3$ , a further quantity of bromine equivalent to 4.30 ml. of 0.1 *N*  $\text{Na}_2\text{S}_2\text{O}_3$ , was set free. This indicates that the equivalent of 5.24 ml. of 0.1 *N* bromine had been added to a double bond. Calculated for one double bond and molecular weight 210, 4.56 ml. Found, 1.15 double bonds + 1.9 atoms bromine substituted.

As a check on the above method, 50.8 mg. of ester were titrated by the pyridine-sulphate-dibromide method [Rosenmund and Kühnhenh, 1923]. 5.92 ml. 0.1 *N* bromine were used up. 50.8 mg. require 4.84 ml. for one double bond assuming a molecular weight of 210. Found 1.23 double bonds.

*Hydroxyl determinations on methyl ester.* The method of West *et al.* [1934] was used. The ester was acetylated with acetic anhydride-pyridine (1:7) and the acetic acid liberated after decomposition with water titrated with 0.1 *N* NaOH and compared with a blank. 51.5 mg. required 1.61 ml. 0.1 *N* NaOH less than the blank. 63.7 mg. required 2.06 ml. 0.1 *N* NaOH less than the blank. OH found 5.29, 5.45%. Calculated for one hydroxyl and molecular weight 210, 8.09%.

As a check on this method, active hydrogen determinations by the Zerevitinoff method were carried out (Roth, Heidelberg). 5.362 mg. gave 0.72 ml.  $\text{CH}_4$  at 25° in pyridine.

7.005 mg. gave 0.98 ml.  $\text{CH}_4$  at 25°. OH found, 6.90, 6.58%.

*Catalytic reduction.* No measurable quantity of hydrogen was absorbed by 250 mg. of ester using a highly active platinum catalyst.

*Oxidation of the methyl ester with alkaline permanganate.* 91 mg. of the methyl ester in 6 ml. of *N* NaOH were oxidised with 0.8 g. of  $\text{KMnO}_4$  at 100°. The slight excess of  $\text{KMnO}_4$  was reduced with  $\text{CH}_3\text{OH}$  and the precipitate filtered off and washed. The filtrate was acidified to Congo red with dilute  $\text{H}_2\text{SO}_4$  and extracted ten times with ether. On removing the ether 26 mg. of a crystalline residue were obtained which was purified by sublimation at 100° under the water-pump. The anhydrous sublimate melted at 182° and was identified as oxalic acid. The calcium salt was analysed. Found Ca, 26.40, 26.38. Calculated for  $\text{CaC}_2\text{O}_4$ ,  $\text{H}_2\text{O}$ , Ca, 27.39%.

#### DISCUSSION.

We have not, as yet, succeeded in crystallising the purified preparations of the sporogenes growth factor or in obtaining a single crystalline derivative. Until we are able to accomplish this, it is not possible to be certain that the characteristic properties of our active oil are those of the sporogenes factor itself. However, we have obtained considerable evidence that the redistilled ester of the active substance is relatively homogeneous. The preparations, after hydrolysis, show a uniform activity (0.04  $\gamma$ /ml.) in stimulating the growth of *Cl. sporogenes* on the amino-acid-deficient medium. Different preparations show a constant elementary composition suggesting a formula of  $\text{C}_{11}\text{H}_{14}\text{O}_4$  or  $\text{C}_{11}\text{H}_{16}\text{O}_4$ . This elementary composition agrees well with the molecular weight determination by freezing point of benzene, with the acid equivalent by titration, with the

bromine titrations indicating the presence of one double bond and with the active hydrogen determinations indicating one hydroxyl group. One oxygen atom is left unaccounted for. Although definite evidence for the presence of a furan ring is still wanting, this possibility is not excluded.

From the evidence presented, it would seem certain that the sporogenes growth factor is an acid of molecular weight about 200 containing at least one hydroxyl group. From the bromine titrations at least one double bond is indicated, although the substance is not reduced by catalytic hydrogenation. Although the elementary composition might suggest the presence of a benzene ring, the sole oxidation product with alkaline permanganate is oxalic acid and no benzoic acid could be detected. Since neither the free acid nor its methyl ester gives aldehydes or ketones on oxidation with lead tetra-acetate, the presence of a glycol or  $\alpha$ -hydroxy-acid may be excluded. The latter possibility is also rendered improbable by the failure of the acid to give a colour reaction with ferric chloride and by the  $p_K'$  value of 4.7, which would suggest that the carboxyl group is at the end of an aliphatic chain.

*Relation of the sporogenes vitamin to other growth factors.*

Recent work on the growth requirements of lower organisms has revealed the existence of a number of accessory factors necessary for their growth. The present study, however, indicates clearly that the sporogenes growth factor is distinct from any of the other well-characterised factors which have been hitherto described.

In their original paper on the "sporogenes vitamin", Knight and Fildes [1933] called attention to the similarity of its properties with those of the plant growth hormones, the auxins [Kögl *et al.* 1933; 1934; Kögl, 1935]. Since that time, however, pure auxin- $\alpha$ -lactone and "heteroauxin" from Prof. Kögl's laboratory have been tested and found to be inactive<sup>1</sup>. We have prepared synthetic "heteroauxin", *i.e.*  $\beta$ -indoleacetic acid, by the method of Majima and Hoshino [1925]. It had no activity when tested in place of the sporogenes growth factor. The present factor is also distinguished from the "auxins" by its great stability to boiling mineral acid and alkali.

Recently a series of papers has appeared from the laboratory of R. J. Williams and his collaborators [1932; 1934] on the nutritional requirements of the "Gebrüder Mayer" strain of yeast. A widely distributed hydroxy-acid of low molecular weight, not yet isolated, is essential for the growth of this and certain other strains of yeast. They have called this factor "pantothenic acid". The concentrated preparations of sporogenes "vitamin" obtained by Knight and Fildes [1933] from yeast appeared to promote growth of the Williams strain of yeast [Edwards, 1933]. We have tested our own active fractions on the Williams strain of "Gebrüder Mayer" yeast, obtained through the National Collection of Type Cultures, and found them to be without growth-promoting effect. An acid factor extractable by butyl alcohol from urine, which stimulates the growth of this strain of yeast, was found to be alkali-labile as reported for "pantothenic acid" by Williams *et al.* [1932].

The sporogenes growth factor is also distinct from the "staphylococcus factor" [Hughes, 1932; Knight, 1935] and from the "bios" whose isolation has just been announced by Kögl [1935]. The last two factors appear to be basic and have altogether different properties from the sporogenes factor.

<sup>1</sup> Private communication from Dr Fildes.

## SUMMARY.

1. A highly active preparation of the sporogenes growth factor, an essential nutrient component for *Cl. sporogenes* and other obligate anaerobes has been obtained. This preparation has the properties of an unsaturated hydroxy-acid of molecular weight about 200. Its methyl ester may be distilled in a high vacuum. The purified product, liberated from the inactive distilled methyl ester by alkaline hydrolysis, invariably promotes visible growth on a medium of otherwise known composition when added in quantities as small as 0.04 $\gamma$  per ml.

2. The relation of the sporogenes growth factor to other accessory growth factors of lower organisms has been discussed.

The author wishes to express his thanks to Dr H. W. Dudley for his helpful suggestions and criticism during the course of this work.

# CCXLIII. A MICROCHEMICAL TEST FOR CHOLINE AND ITS ESTERS IN TISSUE EXTRACTS.

By FREDERICK JOHN BOOTH.

*From the Departments of Physiology and Biochemistry, Queen's University, Belfast.*

*(Received July 25th, 1935.)*

ANY simple test, by means of which we can detect small amounts of free choline and distinguish between it and its water-soluble esters in tissue extracts, is of interest.

It has been known for a long time that periodide solutions are very delicate precipitants for choline. In 1897 Florence used the periodide reagent in testing for semen. In 1901 Bocarius showed that the test was due to the presence of choline in the semen. Staněk [1905; 1906, 1, 2], using his concentrated potassium tri-iodide reagent and determining the amount of nitrogen in the periodide precipitate, was able to estimate the amount of choline present in plant extracts. Roman [1930] worked with solutions of pure choline and used a modified Staněk's reagent. He claims to be able to determine accurately amounts of choline ranging from 5 $\gamma$  to 5 mg. per 1 ml., by estimating the iodine in the enneaiodide precipitate. Carles and Leuret [1934] have studied the microcrystalline characters of the periodide compounds of choline, betaine and trimethylamine in pure solution.

Only scanty data, however, appear in the literature regarding the microscopic characters of choline periodide in tissue extracts. Moreover, there is no account of the microscopic appearances of the periodide compound of any of the choline esters. The present investigation therefore deals with the microcrystalline characters of the periodides of choline and its esters.

In all the experiments the solution to be examined was mixed with Florence's reagent on a clean dry microscopic slide in the proportions suggested by Carles and Leuret, *i.e.* 3 drops of the reagent to 1 drop of the unknown solution. Immediately after covering the preparation, the specimen was examined. The Florence's reagent used had the following composition: potassium iodide 1.65 g.; iodine 2.54 g.; distilled water 30.00 g.

All the solutions examined were neutral or acid to litmus.

## *Choline periodide.*

The microscopic picture varies greatly with the strength of the choline solution:

(a) *1:100 dilution.* Intense precipitate of large black globules of reddish brown hue, presenting an oily appearance. See Fig. 1.

(b) *1:1000 dilution.* In this dilution the most characteristic crystals of choline periodide are seen. They are light brown monoclinic prisms with the characters shown in Fig. 2 and exhibit pleochroism from a pale yellow-brown to dark brown or almost black when examined in plane polarised light. Although the actual strength of the double refraction is indeterminable, it is presumably very low as no high order colours can be seen.

(c) *1:50,000 dilution.* Thin black rods as shown in Fig. 3. In greater dilutions choline cannot be detected. In working with tissue extracts, however, the

sensitivity of the test can be increased about 100-fold by concentration and re-extraction with suitable solvents.

The above findings confirm the admirable work of Carles and Leuret who worked with solutions of pure choline.

Albumin, glycogen and glucose in 0.5% solutions do not interfere with the sensitivity of the test. The influence of lipoids has not been studied.

Fig. 1. Choline periodide, 1 : 100.

Fig. 2. Choline periodide, 1 : 1000, obtained by HCl hydrolysis of the water-soluble precursor from sheep's brain.

Fig. 3. Choline periodide, 1 : 50,000.

Fig. 4. Acetylcholine periodide, 1 : 1000.

In filtered boiling-water extracts of brain, kidney and liver (two parts of boiling water to one part of fresh tissue) there is no free choline within the limits of the test, although choline when added to boiling-water extracts of these organs can be detected in dilutions up to 1 : 50,000. In diseases of the central nervous system such as syphilis and epilepsy the choline content of the cerebrospinal fluid is increased. The cerebrospinal fluid from two cases of general paralysis of the insane was tested. In each case a sample of 20 ml. was examined directly and again after concentration to 1 ml. *in vacuo*. No crystals of choline periodide were found, *i.e.* choline was excluded up to a dilution of 1 : 1,000,000. These results are in agreement with those of Page and Schmidt [1931], who estimated the choline content of the cerebrospinal fluid biologically. They give values ranging from 0.13 to 1.3 mg. choline per litre in syphilis of the nervous system. In the solutions examined up to the present there has been no microcrystalline deposit with Florence's reagent which might be confused with the periodide of choline.

#### *Acetylcholine periodide.*

Unlike that of choline the precipitate is never crystalline. A 1 : 100 solution gives large black globules similar to those of choline. In dilutions of 1 : 500, 1 : 1000 and 1 : 10,000 tiny black granules are seen, which become smaller and

rarer the higher the dilution (Fig. 4). Above a dilution of 1 : 10,000 the granules are no longer seen.

After hydrolysis by 1% NaOH for two minutes at room temperature, making acid to litmus with HCl and then adding Florence's reagent, the typical crystals of choline periodide are seen, provided that the dilution is suitable. That the granules contain acetylcholine is proved by the fact that practically all the acetylcholine present can be found in the periodide precipitate, using Staněk's method for the estimation of choline. These granules are not specific for acetylcholine and the test if it is to be of value in the detection of acetylcholine must be carried out before and after alkaline hydrolysis.

#### *The water-soluble precursor of choline.*

This body was isolated from the kidney by Booth and Milroy [1935] and has since been obtained by Booth from the brain. This ester of choline is not precipitated by Staněk's reagent, as is evident from phosphorus and nitrogen determinations of the precipitate and supernatant fluid. Thus any precipitate, amorphous or crystalline, occurring in solutions of this water-soluble precursor treated with Florence's reagent, cannot be due to this choline-containing compound. Frequently there may be evidence of free choline along with the precursor as is shown by a study of the microcrystalline deposit which may appear, but this only constitutes a small fraction of the choline present. In order that the choline should be set free from this ester acid hydrolysis must be carried out (Fig. 2).

When the mother substance is acetylated it is broken down, the degree of decomposition varying with the vigour of the acetylation, and the choline set free is re-esterified. After removal of the acetyl chloride from the reaction mixture, it gives granules but no crystals with Florence's reagent. After hydrolysis with 1% NaOH for 2 min. at room temperature, however, the typical crystals of choline periodide are seen. The mother substance itself is not decomposed by this mild alkaline hydrolysis.

#### SUMMARY.

1. A micro-chemical test for the detection of small amounts of free choline is described. The test can detect 20 $\gamma$ /100 g. free choline in the tissues, since the sensitivity of the test is 1 : 50,000 and this can be increased 100-fold by appropriate treatment of the extracts.
2. Acetylcholine can be detected as choline after hydrolysis with 1% NaOH for 2 min. at room temperature.
3. The water-soluble ester of choline referred to gives no precipitate with Florence's reagent.

I wish to thank Prof. T. H. Milroy for his invaluable advice during the course of this work.

# CCXLIV. A WATER-SOLUBLE PRECURSOR OF CHOLINE IN THE HUMAN PLACENTA.

By DAVID HENRY SMYTH.

*From the Departments of Physiology and Biochemistry, Queen's University, Belfast.*

*(Received July 25th, 1935.)*

THE presence in the tissues of free choline and its water-soluble precursors has recently attracted attention. Strack *et al.* [1934] have studied the occurrence of choline in the human placenta. They found that aqueous extracts of the placenta contain free choline in amounts which vary according to the length of time during which autolysis is allowed to take place in the uterus before fixation of the tissue in boiling water. After precipitation of the choline in the extracts as a chloroaurate, there remains in solution a choline-containing substance which contains choline and phosphorus in a 1 : 1 ratio. The suggestion is made that this substance may be a sphingomyelin corresponding to a similar substance found in the liver by the same workers [1933]. Booth and Milroy [1935] have isolated from the kidney and more recently from the liver and brain a substance which seems to correspond to that of Strack *et al.* It contains nitrogen and phosphorus in the atomic ratios:

Total N : Amino-N : P = 2 : 1 : 1.

It yields choline on hydrolysis with strong acid.

The problem investigated here is whether the method described by Booth and Milroy can be used for the isolation of a similar substance from the placenta, and also to compare the results obtained for the placenta with those arrived at in the case of the kidney. It will be shown by using this method that there is obtainable from the human placenta a compound such as Booth and Milroy have described in the kidney. This would seem also to correspond to the substance found by Strack *et al.*

## *Experimental procedure.*

For the qualitative detection of free choline the microcrystalline test of Florence was used. A drop of the solution to be tested is mixed with three drops of Florence's periodide solution and examined microscopically for choline periodide crystals. Precipitation with 50% gold chloride was also used. The quantitative assay of choline was done by means of the periodide method of Staněk [1905]. The solution after precipitation with Staněk's periodide solution is passed through a Jena filter. The precipitate is dissolved in aqueous NaOH, and the amount of choline determined by estimation of the nitrogen. Biological estimations of choline were also made after acetylation using as test objects the frog's heart, frog's rectus and mammalian intestine.

The method for isolating the substance containing the bound choline of the placenta is as follows. The placenta is minced in boiling water and the filtered extract precipitated with basic lead acetate. After removal of the lead the filtrate is concentrated to dryness at 37° and extracted with alcohol. The alcoholic extract is precipitated with mercuric chloride, the precipitate extracted with cold water and after removal of the mercury concentrated to dryness,

again extracted with alcohol and re-precipitated with mercuric chloride. A cold-water extract of this contains the bound choline and this can be further purified by a third precipitation with mercuric chloride.

### *Results.*

The isolation of the choline-containing substance can be followed by estimations of the phosphorus and nitrogen at each stage of the procedure. In the case of the kidney, Booth and Milroy found that the basic lead filtrate contained about half the organic phosphorus of the kidney and they showed that this was firmly bound with choline. The phosphorus amounted approximately to 110 mg. per kg. of fresh kidney. In the case of the placenta the amount of phosphorus escaping precipitation with basic lead acetate is very much less and only amounts to 10–20 mg. in each placenta (500 g. of fresh tissue), so that it is evident that such a phosphorus-choline-containing compound as exists in the kidney can only be present in the placenta in very small amounts. If, however, the basic lead filtrate from the kidney be tested with Florence's reagent, it is found to contain no free choline, whilst in the case of the placenta free choline is always present up to about 100 mg. This suggests that the free choline of the placenta may have been derived from a water-soluble precursor such as has been described.

The basic lead filtrate is concentrated to dryness under reduced pressure at 37° and the residue extracted with alcohol. It is found that there is a loss of about 25–50 % of the organic phosphorus during the alcohol extraction. Some of this can be recovered by extracting with acid alcohol. The alcoholic or acid alcoholic extract is now precipitated with mercuric chloride after neutralisation, if necessary, with fused sodium acetate. This results in a copious white precipitate containing both free and bound choline. This precipitate, after washing with alcohol, is extracted with cold water. The mercury compound of the free choline is relatively insoluble in cold water, but if the solution is analysed after removal of the mercury it is found that about 90 % of the organic phosphorus is contained in it. This organic phosphorus, as will be shown later, is in combination with choline so that the mercury salt of the bound choline is readily soluble in cold water. The solution is now neutralised, evaporated at 37° to dryness, extracted with acid alcohol, as the compound is now relatively insoluble in neutral alcohol, and re-precipitated with mercuric chloride.

An aqueous extract of this second mercury precipitate in the case of the kidney contains the choline-containing substance in relatively pure form. On analysis, it is found to contain:

Total N : Amino-N : P in ratio of 2 : 1 : 1.

That the same does not hold in the case of the placenta is seen from the following sets of figures obtained in three different experiments by analysis of the aqueous extract of the second mercury precipitate.

P	:	N
1	:	4.03
1	:	8.20
1	:	3.10

It is evident that the procedure used does not yield a substance of fixed composition, and in all cases the nitrogen value is much higher than would be obtained from the kidney. Owing, however, to the very small amount of organic phosphorus obtainable from the placenta it was considered advisable to examine the nature of the solution obtained before attempting further purification.

To determine the presence or absence of free choline the extract was concentrated at 37° and 50 % gold chloride added. This gave no precipitate. Another fraction was heated at 100° for 8 hours in a sealed tube with an equal volume of 50 % hydrochloric acid. On addition of gold chloride, after neutralisation, a precipitate formed. The melting point of this precipitate (210°) was much lower than that of pure choline chloroaurate. A part of the gold salt was suspended in water and the gold removed by hydrogen sulphide. The filtrate gave a strongly positive microcrystalline test for choline. The presence of choline was further confirmed by acetylating a part of the gold-free solution and testing biologically on the heart of frog, rectus of frog, mammalian blood pressure and intestine. On all these test objects a typical acetylcholine-like action was obtained. The action was inhibited by atropine and did not appear after mild alkaline hydrolysis. One may conclude therefore that the cold-water extract of the second mercury precipitate contains no free choline, but that choline can be set free from it by hydrolysis with strong acid.

In carrying out quantitative estimations of the amounts of free and bound choline by Staněk's periodide method, it was considered advisable to do control experiments in which a known amount of free choline was added to the solution before precipitation. 5 ml. of the extract were precipitated with Staněk's solution, and nitrogen and phosphorus values determined in the filtrate and precipitate. The same procedure was repeated on another sample of 5 ml. to which had been added 2 ml. of choline solution containing 1.736 mg. of choline-nitrogen. The results were as follows:

	5 ml. extract		5 ml. extract + 1.74 mg. choline-N	
	P	N	P	N
	mg.	mg.	mg.	mg.
Before precipitation	0.710	3.05	0.71	4.78
After precipitation: filtrate	0.678	2.88	0.07	2.79
precipitate	0.041	0.09	0.0	1.81

From these figures, it is seen that any free choline added is removed quantitatively, the original extract itself contains only the smallest traces of free choline, and that all the phosphorus and therefore the bound choline escapes precipitation.

The bound choline was estimated by precipitation with Staněk's solution after strong acid hydrolysis (25 % HCl at 100° for 8 hours). The nitrogen and phosphorus values in the periodide filtrate and precipitate in one case were as follows:

	P	N
	mg.	mg.
Extract before hydrolysis	0.70	2.72
Hydrolysed extract after precipitation: filtrate	0.70	2.44
precipitate	0.0	0.31

It is seen that the amount of nitrogen (0.31 mg.) in the form of choline set free by acid hydrolysis bears to the total phosphorus (0.70 mg.) an atomic ratio of 1 : 0.95.

In another case the figures obtained were:

	P	N
	mg.	mg.
Extract before hydrolysis	1.05	4.074
Hydrolysed extract after precipitation: filtrate	—	3.54
precipitate	—	0.56

Again, the amount of nitrogen (0.56 mg.) in the form of bound choline bears to the phosphorus (1.05 mg.) an atomic ratio of 1 : 1.1. It is evident, therefore, that the extract contains no free choline, but contains choline firmly bound which can be liberated by acid hydrolysis, the amount of choline in this form being in equal ratio with the phosphorus in the extract. There is also a large amount of nitrogen present which does not represent either free or bound choline.

The choline-containing substance can be freed from extraneous nitrogen by a third precipitation with mercuric chloride. In one sample after this treatment an analysis of the aqueous extract of the mercury precipitate gave the following figures: total N, 2.313 mg.; amino-N, 1.164 mg.; total P, 2.416 mg.; the atomic ratio being 2.11 : 1.07 : 1.0.

A portion of this extract was taken and after acetylation tested biologically on the frog's rectus. The assay showed the presence of choline and the amount of choline was estimated to correspond with half of the total nitrogen. The amounts present were insufficient for accurate chemical assay.

In contrast with the biological activity of this very small quantity of nitrogen-containing substance was the complete absence of any activity from the non-choline-nitrogen present in the periodide filtrate of the aqueous extract of the second mercury precipitate. In order to show this the filtrate (after removal of the iodine with molecular copper and removal of the copper as a sulphide) was acetylated and tested on the frog's heart, frog's rectus and mammalian intestine.

We have, therefore, obtained from the placenta a substance containing choline-N, amino-N and phosphorus in 1 : 1 : 1 ratio. The amount of the substance isolated has been insufficient for a determination of other possible constituents of the molecule, but it would appear probable that it is similar to that isolated by Booth and Milroy from the kidney, which they regard as a choline phosphoric acid ester of sphingosine, and is also of the same nature as the substance present in the extract obtained by Strack *et al.* from the placenta.

#### SUMMARY.

There is present in aqueous extracts of the human placenta a substance containing bound choline in a water-soluble form. Each molecule of this substance contains one molecule of choline, one of phosphoric acid and one amino-linkage.

The substance is present in only very small quantities in the normally born placenta.

The presence of free choline in the placenta can be readily demonstrated by Florence's microcrystalline test.

My thanks are due to Prof. T. H. Milroy for his advice and assistance during this work.

# CCXLV. A WATER-SOLUBLE PRECURSOR OF CHOLINE FOUND IN THE KIDNEY AND OTHER TISSUES.

By FREDERICK JOHN BOOTH.

*From the Departments of Physiology and Biochemistry, Queen's University, Belfast.*

*(Received July 25th, 1935.)*

IN a recent publication [Booth and Milroy, 1935] brief reference was made to an extremely water-soluble ester of choline which contains in addition phosphoric acid and a compound with many of the characteristics of sphingosine but no fatty acid. It is found in the kidney, brain and in other tissues.

In this paper the method of isolation and the chemical nature of the body as found in the kidney are given in detail, then reference is made to its presence in the brain and liver, and lastly the biological properties are briefly discussed.

## *Method of isolation.*

The fresh finely minced tissue is extracted with boiling water for five minutes. The mixture is then made acid to litmus with glacial acetic acid and boiled for three minutes. The warm extract after filtration and cooling to room temperature is precipitated completely with basic lead acetate and rendered alkaline to litmus with ammonia. The lead precipitate is allowed to settle for two hours and removed. The filtrate, after removal of the lead, is evaporated to dryness under reduced pressure at 40°. A little quartz sand is added and the residue is thoroughly extracted with 3-4 changes of hot absolute alcohol. The precipitate which forms after mixture of the alcoholic extracts is removed and the filtrate is evaporated to dryness at a low temperature under reduced pressure. The dry residue is frequently extracted with alcohol. The combined second alcoholic extracts sometimes give a precipitate which is discarded. The final clear alcoholic extract is precipitated with a saturated solution of  $\text{HgCl}_2$  in absolute alcohol. The precipitate is separated, washed with absolute alcohol and extracted twice with cold water (6°). After removal of the mercury as sulphide, the extract is neutralised to litmus and concentrated under reduced pressure at 40°. The residue is exhaustively extracted with absolute alcohol containing 3-4 %  $\text{HCl}$ . Sufficient alcoholic mercuric chloride for complete precipitation is added to the clear alcoholic extract. Usually only a cloud appears. A saturated solution of fused sodium acetate in alcohol is now added until the supernatant fluid remains clear. The precipitate is separated and washed with absolute alcohol.

As a rule the second  $\text{HgCl}_2$  precipitate is completely soluble in cold water and gives on analysis 2N:1P. If this ratio is still too high another precipitation with  $\text{HgCl}_2$  is necessary. The cold-water extract of the second  $\text{HgCl}_2$  precipitate contains about 50 % of the organic P originally present in the lead filtrate. It is advisable to estimate the amount of phosphorus at every stage. Large losses are usually due to faulty alcohol extraction. If the alcohol is definitely acid in reaction and the mixture thoroughly shaken with quartz sand, the extraction is much more complete. There is no evidence of hydrolysis of the substance by the acid alcohol if the extract is precipitated immediately and the mercury precipitate then separated and washed with alcohol.

After removal of the mercury from the cold-water extract of the final  $\text{HgCl}_2$  precipitate the solution is evaporated to small bulk. The excess chloride in the concentrated solution is removed by silver carbonate and the dissolved silver by careful addition of hydrochloric acid.

Two experiments are quoted, the first in order to illustrate the method of separation and to furnish analyses of the final purified body and the second in order to study the products of acid hydrolysis. In all cases the total N was estimated by the micro-Kjeldahl method, the amino-N by the method of Van Slyke and the P by the method of Fiske and Subbarow [1925].

I. Horse kidney (2.07 kg.).

1. The original boiled extract contained, per kg. fresh tissue, 246 mg. ortho-P and 222 mg. organic P.

2. The basic lead filtrate contained 101 mg. organic P. per kg.

3. A portion of the alcoholic extract of the concentrated lead filtrate, containing 130 mg. organic P with a ratio of 30.8N : 1 P, was taken for precipitation with  $\text{HgCl}_2$ .

4. The cold-water extract of the first  $\text{HgCl}_2$  precipitate contained 118 mg. organic P and had a ratio of 8.1N : 1 P.

5. The similar extract of the second precipitate contained 84.5 mg. organic P (2.8N : 1 P).

6. A portion of the extract of the third precipitate, which gave a 2N : 1 P ratio, was freed from excess chloride and dried to constant weight. On analysis the specimen (after deduction of the traces of chloride not removed) gave the following results:

	Found %	Calc. for $\text{C}_{23}\text{H}_{51}\text{O}_6\text{N}_2\text{P}$ %
Organic P	6.41	6.43
Total N	5.88	5.80
Amino-N	2.98	2.90

II. Ox kidney (1.61 kg.).

1. The basic lead filtrate contained 137.5 mg. organic P per kg.

2. The extract of the first  $\text{HgCl}_2$  precipitate contained 90.6 mg. organic P (4.17N : 1 P).

3. The extract of the second precipitate gave on analysis: 65.8 mg. organic P and 58.0 mg. total N (1.95N : 1 P). Calculating the choline value from half the nitrogen, the amount of choline chloride in the bound form should be 288 mg. After acid hydrolysis of this extract 835 mg. chloroaurate (M.P. 233°, Au 44.44 %) were obtained. This corresponds to 263 mg. choline chloride. The chloroaurate was free from amino-N and P, and on testing biologically was found both qualitatively and quantitatively to be identical with the salt of choline.

*Chemical nature.*

The large amount of the acid-soluble organic phosphorus of the kidney which escapes basic lead acetate precipitation is evident from Tables I and II.

Table I.

Exp. no.	Source and moist weight of kidney tissue g.	Boiling water extract		Basic lead filtrate, mg. organic P per kg.	% organic P escaping precipitation
		mg. ortho-P per kg.	mg. organic P per kg.		
1	1000 horse	225	191	114	59.7
2	2070 horse	246	222	101	45.5
3	825 ox	340	240	127	53.0
4	1900 ox	313	243	143	58.8

On an average 54.2 % of the acid-soluble organic P of the kidney escapes basic lead precipitation.

Table II gives the absolute yields of organic P which escape basic lead precipitation.

Table II.

Exp. no.	Moist weight and source of kidney tissue (g.)	Basic lead filtrate mg. organic P per kg.
1	1500 horse	85.4
2	1250 "	90.6
3	2425 "	102.5
4	1260 "	93.0
5	2250 "	109.5
6	1280 "	100.8
7	1330 "	90.2
8	430 ox	155.6
9	650 "	132.9
10	530 "	128.3

On an average 108.8 mg. organic P per kg. escape precipitation by basic lead acetate.

The P-containing substance present in the lead filtrate of the kidney is extremely soluble in water. It can be extracted almost completely from dry residues of the lead-free filtrate by hot absolute alcohol. After precipitation with mercuric chloride, the substance is only slightly soluble in neutral alcohol but is readily dissolved by alcohol containing 3-4 % HCl. It is precipitated from acid alcohol by fused sodium acetate along with much nitrogenous impurity. It is insoluble in acetone, ether and chloroform. It can be precipitated from aqueous and alcoholic solution by a large excess of acetone but incompletely and along with nitrogenous impurity.

The Ba, Ca, Ag, Pb, Cu and Hg salts are all soluble in water. The double salt with gold and the periodide compound are also soluble in water. 25 % phosphotungstic acid in 5 %  $\text{H}_2\text{SO}_4$  precipitates the P-containing substance incompletely and this method of separation is very unsatisfactory. The Ag and Ba salts are soluble in alcohol, but after baryta hydrolysis the Ba salt seems to lose its solubility. The double salts with cadmium chloride and mercuric chloride are both insoluble in alcohol.

The purified substance is yellow and resinous and on analysis shows approximately the composition of a compound ester of choline and sphingosine with phosphoric acid. The optical activity is apparently low as no rotation could be detected in a solution of the pure substance containing 4 mg. organic P per 1 ml. (=6.22 % choline-sphingosinephosphoric acid), when examined in a 1 dm. tube.

In Fig. 1 the hydrolysis curves of the P-containing substance found in the lead filtrate of the kidney and liver are compared with that of calcium glycerophosphate (Merck's neutral). Hydrolysis was carried out with 1.53N  $\text{H}_2\text{SO}_4$  at 100°. In all three cases the phosphoric acid is firmly bound.

Half the nitrogen of the pure substance is present in the form of choline. All the choline is set free by 20 % HCl at 100° in 8 hours. The chloroaurate obtained from the HCl hydrolysate melts at 233° (sharp), instead of 252°, but is otherwise identical with that of choline. The amount of choline obtainable from the substance can only be given approximately, but from 250 to 300 mg. choline chloride per kg. fresh kidney have been obtained by acid hydrolysis of the purified substance.

The N and P contents of this ester and the fact that half the nitrogen is in the amino-form suggest strongly the presence of sphingosine, although it has not been satisfactorily isolated. There is no fatty acid or reducing carbohydrate among the products of hydrolysis.

Fig. 1. A,  $\bigcirc$ — $\bigcirc$  lead filtrate (kidney); B,  $\times$ — $\times$  lead filtrate (liver); C,  $\square$ — $\square$  calcium glycerophosphate.

All these facts agree with the suggestion that the substance is the choline ester of sphingosinephosphoric acid. The question as to whether all the organic P present in the basic lead filtrate is of the same type is still uncertain. Naturally traces of the well-known phosphoric acid esters will escape lead precipitation. About 50 % of the organic phosphorus originally present in the lead filtrate can be obtained in the pure ester form. How much of the remaining 50 % is in the same form it is impossible to say.

Strack *et al.* [1933; 1934] describe a similar substance which they found in the liver and placenta and from which choline is readily set free in acid solution. They regard the substance from the liver as a water-soluble sphingomyelin. They state that the quantity available did not allow them to identify the fatty acids but they conclude that the contents of P, total N, amino-N and choline-N correspond to a sphingomyelin of mol. wt. 800 [Thierfelder and Klenk, 1930]. They refer to half the nitrogen being in the amino-form (Van Slyke determination), although no such nitrogen is present when the sphingosine is linked to the fatty acid as in the ceramides, sphingomyelins and cerebrosides. They also state that it is possibly the same body as that described by Fränkel *et al.* [1933], although the sphingomyelin obtained from the liver by the latter authors was only slightly soluble in water, forming a colloidal solution.

Karrer and Salomon [1926] have obtained by partial baryta hydrolysis of lecithin a choline ester of glycerophosphoric acid. Unlike that of glycerophosphate the Ba salt of this ester is fairly soluble in alcohol.

#### *Presence in the brain and liver.*

The points on which the identity of the ester can be established with reasonable certainty are as follows:

(1) It contains organic P in a form not precipitable by basic lead acetate and is soluble in water and alcohol.

(2) The double salt with mercuric chloride is insoluble in alcohol but is extremely soluble in cold water.

(3) It is not precipitated by 50 % gold chloride.

(4) It shows a ratio of 2N : 1P, half of the nitrogen being in the amino-form, and yields choline on hydrolysis.

*Brain.* In the following two experiments the brain tissue was worked up in the way described above. Unfortunately the amount of material available did not allow of complete purification, and so in the first experiment the second mercuric chloride precipitate was examined for bound choline by acid hydrolysis and precipitation with 50 % gold chloride and in the second by similar hydrolysis and precipitation with Florence's reagent. The values given are calculated for 1 kg. moist tissue.

I. Sheep brain (290 g.).

1. The boiling-water extract contained 247 mg. organic P.

2. The lead filtrate contained 77 mg. organic P.

3. The extract of the first  $\text{HgCl}_2$  precipitate gave on analysis 49.2 mg. organic P (7.42N : 1P).

4. The extract of the second precipitate contained 36.3 mg. organic P (3.6N : 1P). After removal of the Hg and neutralisation to litmus, the extract was concentrated to 2 ml. and acidified (20 % HCl). A small sample was tested immediately with gold chloride. There was no precipitate. After hydrolysis for 9 hours at  $100^\circ$ , 486 mg. chloroaurate (m.p.  $252^\circ$ , Au 44.46 %) were obtained. This corresponds to 153 mg. choline chloride. A portion of the chloroaurate after removal of the gold was acetylated and tested biologically. It was found to have the same action as acetylcholine. The chloroaurate is therefore identical with that of choline. Assuming a ratio of 1P : 1 choline in the second sublimate precipitate, it follows that 93.6 % of the bound choline can be recovered as the chloroaurate after acid hydrolysis.

II. Horse brain (580 g.).

1. The lead filtrate contained 51 mg. organic P.

2. The cold water extract of the first  $\text{HgCl}_2$  precipitate contained 35 mg. organic P.

3. The extract of the second precipitate gave on analysis 25 mg. organic P (4.3N : 1P). The extract gave no crystals of choline periodide but after hydrolysis these could be easily demonstrated.

There is therefore present in the brain a water-soluble P-containing substance which yields choline on hydrolysis. From the partly purified body 153 mg. choline chloride per kg. have been obtained by acid hydrolysis. The ester is probably identical with that found in the kidney. A third precipitation with  $\text{HgCl}_2$  would almost certainly reduce the N : P ratio to 2 : 1.

*Liver.* There is definite evidence of the choline ester in the liver. In Fig. 1 the hydrolysis curve of the P-containing substance in the lead filtrate is compared with that of the similar substance in the kidney. The curves stand in good agreement. In one experiment a 2N : 1P ratio was reached in the second mercuric chloride precipitate and half the nitrogen was accounted for by choline, using Staněk's method of estimation [1905; 1906, 1, 2].

#### *Biological properties.*

The biological study has been confined to the action of the ester, before and after acetylation, and of the acetylated base derived from this ester by acid hydrolysis, gold precipitation and acetylation, on the usual choline test objects. The strengths of solutions used are given in terms of nitrogen values.

The mother substance when freshly prepared has no action on the eserinated frog's rectus. Sometimes it shows a slight activity in strong concentrations due

to the presence of free choline. The acetylated mother substance (Fig. 2) is qualitatively identical with acetylcholine in its action. Acetylcholine has been demonstrated in the reaction mixture by the periodide reagent and the degree of activity depends on the amount of decomposition during acetylation and the quantity of acetylcholine thus formed. The acetylated base (Fig. 3) behaves qualitatively and quantitatively exactly like acetylcholine. The action is prevented in all cases by atropine.

Fig. 2.

Fig. 2. Rabbit's intestine. *M*, acetylated mother substance, half N-value as acetylcholine = 1/1,748,000. *M*<sub>1</sub>, same as *M* after atropine.

Fig. 3.

Fig. 3. Eserinised rectus of frog. 1. Acetylcholine chloride, 1/500,000. 2. Acetylated base from mother substance (brain) N-value — acetylcholine 1/450,000. 3. 2 after atropine.

#### SUMMARY.

1. An extremely water-soluble substance with chemical properties which indicate that it is the choline ester of sphingosinephosphoric acid has been isolated. Over 260 mg. choline chloride per kg. fresh kidney may be obtained by acid hydrolysis of the pure substance and over 150 mg. choline chloride per kg. fresh brain by acid hydrolysis of the partly purified substance.

2. The method of isolation depends on the precipitability of the ester from alcoholic solution as the double salt of  $\text{HgCl}_2$  and the solubility of this double salt in cold water ( $6^\circ$ ). Purification is effected by repeated precipitation with  $\text{HgCl}_2$ .

3. The general characters of the water-soluble ester of choline found in the brain and liver indicate that it belongs to the same class as the one met with in the kidney.

4. The ester has no action on the eserinised rectus of the frog. During acetylation it is decomposed and the acetylated derivative has all the chemical and biological properties of acetylcholine.

The author wishes to acknowledge that throughout the whole of this work he has had the invaluable guidance and co-operation of Prof. T. H. Milroy.

# CCXLVI. METABOLISM OF AMINO-ACIDS.

## V. THE CONVERSION OF PROLINE INTO GLUTAMIC ACID IN KIDNEY.

BY HANS WEIL-MALHERBE AND HANS ADOLF KREBS.

*From the Biochemical Laboratory, Cambridge.*

*(Received July 11th, 1935.)*

### I. *Formation of amide-nitrogen from proline and hydroxyproline.*

It was shown in the preceding paper of this series [Krebs, 1935, 2] that kidney of rabbit and guinea-pig converts ammonium glutamate into glutamine. When experiments were carried out to determine whether other amino-acids could form amides, it was found that only proline and hydroxyproline behaved similarly to glutamic acid.

If proline or hydroxyproline and ammonium salts are added to kidney, ammonia disappears and the ammonia which has disappeared is found in the solution as amide-nitrogen (Table I). The rate of amide-nitrogen formation is smaller in the presence of proline or hydroxyproline than it is in the presence of glutamic acid. With proline the rate of amide-nitrogen formation is 20–30 %, whilst with hydroxyproline it is 5–10 %, of the rate obtained with *L*-(+)-glutamic acid.

When proline or hydroxyproline (without ammonia) is added to kidney slices, less ammonia is formed than in their absence; instead of ammonia amide-nitrogen is found in the solution (Table I).

Proline and hydroxyproline also cause an increase in the oxygen uptake of kidney as previously observed [Krebs, 1933, 1; Bernheim and Bernheim, 1934]. This increase amounts to 60–100 % and is about the same with proline and hydroxyproline (Tables I and II).

### II. *Formation of amino-nitrogen from proline and hydroxyproline.*

The amide formed in the presence of proline and hydroxyproline behaves like glutamine on acid hydrolysis (complete hydrolysis in 5 % sulphuric acid at 100° in 5 min.). This makes it probable that the amide formed from proline and hydroxyproline is glutamine. A conversion of proline into glutamine is conceivable, the primary step being the oxidation of proline to glutamic acid according to the equation:

In this reaction amino-nitrogen would be formed; we determined the amino-nitrogen by Van Slyke's method and found an amount of the expected order of magnitude (Table II). This shows that the oxidation of proline and hydroxyproline actually yields an amino-compound.

Under anaerobic conditions no amino-nitrogen is formed from proline or hydroxyproline (Table II). Only by oxidation can the pyrrolidine ring be opened by kidney tissue.

Table I. *Disappearance of ammonia and formation of amide-nitrogen in the presence of proline and hydroxyproline in kidney.*

(Phosphate saline, 37.5°; for experimental details see Krebs [1935, 1, 2].)

\* Anaerobic experiment.

III. Isolation of  $\alpha$ -ketoglutaric acid.

Since amino-acids are oxidised by kidney slices, it is not possible to accumulate the amino-acid which is formed from proline in sufficient quantity for isolation. It was possible however, by adding arsenious oxide [Krebs, 1933, 2], to check the oxidation of the amino-acid at the stage of the ketonic acid and to identify the latter as  $\alpha$ -ketoglutaric acid.

Slices of rabbit kidney cortex (1.3 g. dry weight) were suspended in 150 ml. bicarbonate saline containing  $M/25$   $l(-)$  proline and  $M/380$  arsenious oxide. The suspension was placed in four flasks of the shape previously described [Krebs, 1933, 1], the gas space being filled with 5%  $\text{CO}_2$  in  $\text{O}_2$ . The vessels were shaken for 4 hours at  $37.5^\circ$  after which the slices were removed and the protein was precipitated with trichloroacetic acid. The clear solution was concentrated *in vacuo* to about 60 ml. and 5 ml. of a solution of 2:4-dinitrophenylhydrazine (0.7% in  $2N\text{HCl}$ ) added. After a few minutes a precipitate began to separate. The fluid was kept on ice and on the following day the precipitate was removed by centrifuging and washed with dilute  $\text{HCl}$  and water. The dried precipitate weighed 63.7 mg.; it showed two different forms of crystals—fine needles and whetstone crystals, arranged in rosettes. The melting-point of this crude product was  $209.5^\circ$  (uncorrected). The crystals were very readily soluble in  $N$  sodium bicarbonate, giving a pale brown solution. On acidification with  $\text{HCl}$  58 mg. separated out (m.p.  $211.5^\circ$ , uncorrected). This material was not completely soluble in ethyl alcohol. On dilution of the alcoholic solution with water crystals of both types were obtained again (48.2 mg., m.p.  $215^\circ$ ). The product was now recrystallised from ethyl acetate. Again a small amount of insoluble residue remained. This time the recrystallised material was uniform and consisted of fine needles. The colour was lemon yellow whereas the former products were orange; m.p.  $222^\circ$  (uncorrected). The dinitrophenylhydrazone of pure  $\alpha$ -ketoglutaric acid has the same colour, the same melting-point and the same solubility in  $N$  sodium bicarbonate [Krebs, 1933, 2]. Mixed melting-point  $222^\circ$ . (Found (Dr Weiler, Oxford): C, 40.59%; H, 3.42%; N, 16.71%.  $\text{C}_{11}\text{H}_{10}\text{O}_8\text{N}_4$  requires C, 40.44%; H, 3.09%; N, 17.18%.)

In the mother-liquor of the first dinitrophenylhydrazone precipitate 2.73 mg. ammonia-N and 2.04 mg. amide-N were found. 63.7 mg. dinitrophenylhydrazone of  $\alpha$ -ketoglutaric acid are equivalent to 2.77 mg. amino-N. Thus less  $\alpha$ -ketoglutaric acid is found than is calculated from the amount of ammonia and amide-N. This is explained by the fact that arsenious oxide does not completely inhibit the breakdown of the ketonic acid formed.

When hydroxyproline was added as substrate instead of proline no appreciable amounts of a dinitrophenylhydrazone were found.

## IV. Pyrrolidonecarboxylic acid.

It might be assumed that the first step in the oxidation of proline is the formation of pyrrolidonecarboxylic acid, according to the equation:

We therefore studied the behaviour of this supposed intermediate in guinea-pig kidney.  $l(-)$  Pyrrolidonecarboxylic acid was prepared from  $l(+)$  glutamic acid

according to Abderhalden and Kautzsch [1910]. The substance was free from glutamic acid (no amino-N).

Pyrrolidonecarboxylic acid, when added to guinea-pig kidney in neutral solution, had no effect on the oxygen uptake, on the ammonia consumption or on the formation of amino- and amide-nitrogen. This leads to the conclusion that pyrrolidonecarboxylic acid is not the intermediate, and that scheme (2) does not apply to the oxidation of proline in kidney.

Abderhalden and Hanslian [1912] observed that *l*-(—) pyrrolidonecarboxylic acid is metabolised when fed to a rabbit. The path of the breakdown is unknown however: we were unable to detect an enzyme which hydrolyses pyrrolidonecarboxylic acid to glutamic acid either in slices or in extracts of guinea-pig or rabbit kidney.

#### V. Inhibition of the oxidation of proline by oxidisable substances.

It was shown in section II that amino-nitrogen is formed when proline is oxidised. The formation of amino-nitrogen can be used to follow the oxidation of proline under various conditions. The formation of amino-nitrogen from proline is depressed when lactate or pyruvate is added (Table III), because these

Table III. *Oxidation of proline in the presence of lactate and pyruvate.*

(Guinea-pig kidney, 37.5°, 2 hours.				
mg. tissue	Substrate added (final concentrations)	$Q_{O_2}$	Amino-N formed ( $\mu$ l.)	$Q_{\text{amino-N}}$
18.04	0	— 14.9	90.8	2.5
18.36	<i>M</i> /100 <i>dl</i> -lactate	— 23.2	103	2.8
14.79	<i>M</i> /100 pyruvate	— 23.2	—	—
16.75	<i>M</i> /100 <i>l</i> -(—) proline	— 27.7	433	12.9
18.19	<i>M</i> /100 <i>dl</i> -lactate + <i>M</i> /100 <i>l</i> -(—) proline	— 24.3	272	7.5
17.22	<i>M</i> /100 pyruvate + <i>M</i> /100 <i>l</i> -(—) proline	— 24.6	319	9.2

substances are oxidised instead of proline. Each substrate—proline, lactate or pyruvate—causes an increase in the oxygen uptake; but two substrates together do not yield a summation of the separate increments [see Krebs, 1935, 1]. These experiments seem to indicate that the activation of oxygen is the same for proline and for the other substrates; but it is still an open question whether the activation of proline (by a “dehydrogenase”) is specific or whether it is the same as for the *l*-amino-acids. The oxidation of proline occurs only in tissues which oxidise *l*-amino-acids, that is in kidney and liver, and the rates of oxidation seem to run parallel: proline and *l*-amino-acids are oxidised about ten times more rapidly in kidney than in liver. We found no oxidation of proline in brain, muscle, intestine or spleen of the guinea-pig.

The oxidation of proline is inhibited to the same extent as the oxidation of *l*-amino-acids by cyanide and by octyl alcohol. In the minced kidney (Latapie mincer) proline is still oxidised if the “brei” is suspended in a small volume of liquid, but the oxidation ceases if more than four volumes of liquid are used for dilution [see also Bernheim and Bernheim, 1932].

#### VI. Conclusions.

Three products of oxidation of proline have been found in this investigation:  $\alpha$ -ketoglutaric acid and ammonia appear when the kidney is poisoned with arsenious oxide; an acid amide which reacts like glutamine is found when

ammonia is added. The metabolism of proline in kidney may therefore be formulated in the following way:

The intermediate stages between proline and glutamic acid are obscure. Pyrrolidonecarboxylic acid is not the intermediate, since it is not metabolised to a measurable extent.

Hydroxyproline also causes the formation of an acid amide which reacts like glutamine. Although one might hesitate to postulate the formation of glutamine from hydroxyproline, since this would necessitate the reduction of the  $\gamma$ -hydroxy-group, it is possible that this reduction is the first step in the breakdown of hydroxyproline, proline thus being an intermediate. Hydroxyproline is certainly not the intermediate in the oxidation of proline since proline reacts more rapidly than hydroxyproline in respect of the formation of amino-nitrogen and of amide-nitrogen.

We are indebted to Sir F. G. Hopkins for his kind interest and encouragement during the course of this work.

# CCXLVII. KETOGENESIS-ANTI-KETOGENESIS.

## I. THE INFLUENCE OF AMMONIUM CHLORIDE ON KETONE-BODY FORMATION IN LIVER.

By NORMAN LOWTHER EDSON.

*From the Biochemical Laboratory, Cambridge.*

*(Received July 24th, 1935.)*

ANNAU [1934] investigated the formation of acetoacetic acid in chopped liver of the rabbit and discovered that in the presence of pyruvic acid ammonium salts caused a four- or five-fold increase in the production of acetoacetic acid. Since this effect of ammonia seemed likely to be of importance in ketogenesis from the amino-acids and from other substances, it was decided to examine the phenomenon in greater detail. For this purpose the tissue slice technique was chosen. This method has already been used in ketogenic studies by Quastel and Wheatley [1933; 1934].

### METHODS.

#### *Animals.*

It was found that suitable animals were young male rats (3-6 months) of a uniform strain bred in the laboratory. These animals were fed on a stock diet which included liberal amounts of bread and milk, and they were permitted as much food as they would take.

#### *Manometric procedure.*

The liver slices (20-30 mg. dry weight), immersed in 2 ml. of phosphate saline [Krebs, 1933], were contained in conical Warburg vessels, which were filled with oxygen. The flasks were shaken for 2 hours in a thermostat at 37.5° and the oxygen uptake was measured in all experiments. At the end of 2 hours the vessels were quickly conveyed to a dish containing ice, and the slices were washed before being transferred to the weighing cups.

After the filter-paper absorbers had been removed from the inner cups of the Warburg vessels, the excess caustic alkali was soaked up with filter-paper. Then 0.2 ml. 2*N* H<sub>2</sub>SO<sub>4</sub> was delivered into each inner cup and the inside wall rubbed down with the tip of the pipette. Finally, acetoacetic acid was determined by one or other of the methods described below.

#### *Methods of estimation of acetoacetic acid ( $\beta$ -ketonic acids)<sup>1</sup>.*

##### *1. Aniline citrate method.*

Aniline, and some other primary amines, possess the property of accelerating the spontaneous decarboxylation of  $\beta$ -ketonic acids, which is most rapid at  $p_H$  4. The kinetics of this catalysis have been studied exhaustively by Ljunggren [1925]. Manometric measurement of the liberated CO<sub>2</sub> affords a simple and convenient means of determining  $\beta$ -ketonic acids. The aniline method was introduced by Ostern [1933] for the determination of oxaloacetic acid, and aniline hydrochloride was employed by Quastel and Wheatley [1933] for acetoacetic acid. A much higher concentration of catalyst may be achieved by using the

<sup>1</sup> These methods were worked out in collaboration with Dr H. A. Krebs.

more soluble aniline citrate, and as a result it becomes possible to work with reasonable speed at a low temperature (25°). This has the advantage of reducing the spontaneous decomposition of acetoacetic acid to very low proportions.

*Reagents.* (i) 50 % citric acid solution.

(ii) Aniline citrate. Equal volumes of aniline and 50 % citric acid; the mixture reacts strongly acid.

*Procedure.* To the fluid in the main compartment of the Warburg vessel is added 0.3 ml. 50 % citric acid and to the side-bulb 0.4 ml. aniline citrate. A thermobarometer containing 2.0 ml. of water is treated in the same way. In order to equilibrate and to decompose such bicarbonate as may be present, the vessels are shaken gently for 20 min. in a thermostat at 25°. Then the contents of the vessels, including those of the thermobarometer, are mixed, and pressure readings taken every 10 min. until constancy is attained. The time required, inclusive of equilibration, is 1–1½ hours. It is necessary to charge the thermobarometer with aniline citrate, because the dilution of this concentrated solution leads to a fall of pressure amounting to a few mm. 1 mg. acetoacetic acid gives 220  $\mu$ l. CO<sub>2</sub> at N.T.P. 1 millimol acetoacetic acid = 22,400  $\mu$ l. CO<sub>2</sub>.

## 2. *o*-Phenylenediamine citrate method.

It has been shown by Beniya [1934] that *o*-phenylenediamine is more effective in decomposing  $\beta$ -ketonic acids catalytically than any other primary amine so far examined. Since *o*-phenylenediamine is three or four times as active as aniline at  $p_{H}$  4, the period of the determination may be reduced to 30–40 min. inclusive of equilibration.

*Reagents employed.* (i) 0.1 ml. *o*-phenylenediamine citrate in the side-bulb. (10 g. *o*-phenylenediamine are dissolved in 25 g. 50 % citric acid solution.)

(ii) 0.3 ml. 50 % citric acid added to the fluid in the main compartment.

It is essential that the *o*-phenylenediamine citrate should be freshly prepared, because after an interval of 4–6 weeks it acquires the property of decomposing certain  $\alpha$ -ketonic acids, namely pyruvic and phenylpyruvic acids, and possibly others. This matured reagent is a carboxylase model resembling those described by Langenbeck [1933]; it differs in that it is active in aqueous solution. As it undergoes autoxidation, the solution becomes dark red, until eventually a brownish red crystalline material separates. Preliminary experiments have indicated that the new activity of the solution is probably due to a mixture of *o*-phenylenediamine and 2 : 3-diaminophenazine which is one of the products of oxidation. Fresh solutions of *o*-phenylenediamine (citrate or hydrochloride) have no action on  $\alpha$ -ketonic acids.

*Procedure.* In the main the procedure is similar to that employed in the case of aniline citrate, and the order of accuracy is the same, but since *o*-phenylenediamine undergoes slow autoxidation, it becomes necessary to fill the vessels with nitrogen before introducing them into the 25° thermostat. Commercial nitrogen containing less than 1 % oxygen suffices.

## 3. *Micro-determination of acetone bodies with Denigès' reagent.*

Since the method of Van Slyke [1917] possesses the merit of achieving some degree of specificity [Peters and Van Slyke, 1932], it has been adapted to the micro-scale requirements of tissue slice work. Van Slyke determines the acetone bodies either by weighing the acetone-mercury compound, or by titrating with potassium iodide after conversion into mercuric chloride. In micro-analyses it has been found expedient to follow the principle of Van Slyke's procedure as far as the separation of the acetone-mercury compound and the conversion into mercuric chloride, and then to titrate the mercury according to Rupp [1906; 1907].

*Reagents.* 20% copper sulphate; 10% calcium hydroxide suspension; Denigès' reagent: (1) 50%  $\text{H}_2\text{SO}_4$ , (2) mercuric sulphate solution (73 g.  $\text{HgO}$  dissolved in 1 l. 4*N*  $\text{H}_2\text{SO}_4$ ); *N*  $\text{HCl}$ ; 35% formaldehyde; 3% potassium iodide; 7.5*N*  $\text{NaOH}$ ; glacial acetic acid; 0.01*N* iodine; 0.01*N* thiosulphate; starch solution; 5% potassium dichromate.

*Apparatus.* 10 ml. micro-burette; sintered glass funnels, Jena 3 G 3 and 3 G 4; hard glass flasks (r.b.) with ground-in joints to fit condensers (20 cm., double-surfaced).

(a) *Determination of acetoacetic acid.* After removal of the slices and excess caustic alkali from the Warburg vessels, there is added 1.0 ml. of a copper-lime reagent, consisting of 0.5 ml. 20% copper sulphate and 0.5 ml. 10% calcium hydroxide suspension. This serves the double function of deproteinisation and removal of interfering carbohydrate substances. No  $\text{H}_2\text{SO}_4$  is placed in the inner cup.

The fluid is transferred to a 25 ml. Erlenmeyer flask, after which the Warburg vessel is rinsed twice with 5.0 ml. portions of distilled water. The vessel contents and washings are made up to a total volume of 15.0 ml. and allowed to stand for 20 min. before filtering.

After filtration 12.5 ml. of the clear fluid are pipetted into a round-bottomed hard glass flask provided with a ground joint for the condenser. Denigès' reagent, consisting of 1.0 ml. 50%  $\text{H}_2\text{SO}_4$  and 3.5 ml. mercuric sulphate solution, is then added, and the mixture boiled gently for 30 min. under an efficient reflux.

The acetone-mercury compound is filtered with suction on a sintered glass funnel (Jena 3 G 4), and washed with 12.5 ml. of distilled water, two 5.0 ml. portions of which are used for rinsing the flask. The filtrate ( $F_\beta$ ) is used for the determination of  $\beta$ -hydroxybutyric acid.

The precipitate is dissolved on the funnel in 5.0 ml. of warm *N*  $\text{HCl}$ , or in such an additional measured volume as may be necessary, and the mercuric chloride solution sucked into the filter-flask. The filter is washed thoroughly with distilled water. To the mercuric chloride solution so obtained are added in succession 0.5 ml. 35% formaldehyde, 5.0 ml. 3%  $\text{KI}$  and 1.0 ml. 7.5*N*  $\text{NaOH}$  (1.0 ml.  $\text{NaOH}$  must be added for every 5.0 ml. *N*  $\text{HCl}$  used in dissolving the precipitate). The solution is permitted to stand for at least 2 min., it is agitated, and then are added in order 0.5 ml. glacial acetic acid (0.5 ml. for each ml. of caustic alkali) and 10.0 ml. 0.01*N* iodine solution. The total volume of fluid is about 30 ml. An additional 10.0 ml. of iodine may prove necessary. It is important that the fluid should smell strongly of acetic acid after acidification. Finally, the excess iodine is titrated with 0.01*N* thiosulphate. The blank for the reagents is about 0.1–0.2 ml. of thiosulphate.

Taking the aliquot into account, 1.0 ml. 0.01*N* iodine = 0.138 mg. acetoacetic acid = 30.2  $\mu\text{l. CO}_2$ .

(b) *Determination of  $\beta$ -hydroxybutyric acid.* The filtrate,  $F_\beta$ , from (a) is returned to the boiling flask and heated to boiling. 1.0 ml. 5% potassium dichromate is added through the top of the condenser, after which the boiling is continued gently for 90 min. Care is needed in order to avoid bumping. The acetone-mercury compound is filtered on a sintered glass funnel (Jena 3 G 3), without suction and while the fluid is still warm. The flask is rinsed thoroughly with distilled water, and the washings run through the funnel until the filtrate is free from dichromate. The precipitate is dissolved in 5.0 ml. of warm *N*  $\text{HCl}$ , but as there is a tendency for grains of the precipitate to adhere to the boiling flask, it is advisable to rinse the flask with the acid, which is subsequently poured on the filter. The funnel is washed thoroughly with distilled water, and the mercury in filtrate and washings estimated by titration as before.

Taking the original aliquot into account, 1.0 ml. 0.01*N* iodine = 0.185 mg.  $\beta$ -hydroxybutyric acid = 39.9  $\mu$ l. CO<sub>2</sub>.

This method has been used as a check on the manometric determinations, and it has also provided a serviceable means of estimating  $\beta$ -hydroxybutyric acid. The reagents used in the first part of the procedure—the formation of the acetone-mercury compound—are those of Van Slyke, and they are employed in the same concentrations, although the actual quantities are much smaller. Since the reagents are employed in proportions identical with those of the original method, Van Slyke's empirical factors are applicable.

Rupp's method was originally designed for titration of large quantities of mercury. The reagents have been used in Rupp's proportions, but the actual amounts are those required for micro-determinations.

The validity of the method was tested on solutions containing (1)  $\beta$ -hydroxybutyric acid, and (2) mercuric chloride in concentrations corresponding to the order of acetone-body formation expected in tissue slice work. The results are given in Tables I and II.

Table I. *Estimation of  $\beta$ -hydroxybutyric and acetoacetic acids.*

Amount of acid in solution mg.	Titration. 0.01 <i>N</i> iodine used in oxidation of mercury ml.	Amount found mg.	% recovered
(1) <i>l</i> -Hydroxybutyric acid:			
1.04 (sodium salt)	6.71	1.04	100.0
0.50 (calcium-zinc salt)	3.34	0.52	104.0
0.20 ..	1.21	0.19	95.0
0.15 ..	0.94	0.15	100.0
0.10 ..	0.72	0.11	110.0
0.05 ..	0.32	0.05	100.0

1.0 ml. 0.01 *N* I = 0.154 mg. hydroxybutyric acid.

(2) Acetoacetic acid:			
1.02 (sodium salt)	9.49	1.09	106.9

1.0 ml. 0.01 *N* I = 0.115 mg. acetoacetic acid.

0.1 *M* sodium acetoacetate was prepared by the method of Ljunggren [1924].

The figures tend to be too high, but are within the limits of accuracy ( $\pm 10\%$ ) of the Van Slyke method.

Table II. *Estimation of mercuric chloride.*

Amount of mercuric chloride (recrystallised) in solution mg.	Titration. 0.01 <i>N</i> I used in oxidation of mercury 1 ml. = 1.357 mg. HgCl <sub>2</sub> ml.	Amount found mg.	% recovered
10.22	7.34	9.96	97.5
7.67	5.50	7.46	97.3
5.11	3.68	4.99	97.7
2.56	1.81	2.46	96.1
2.04	1.43	1.94	95.1
1.53	1.09	1.48	96.7
1.02	0.73	0.99	97.1

The recovery values are consistently low, whereas those for  $\beta$ -hydroxybutyric acid tend to be high when Van Slyke's factor is employed (1 mol.  $\beta$ -hydroxybutyric acid yields 0.75 mol. acetone). This was not due to the trace of dichromate adhering to the mercury-acetone compound, because a much larger

quantity of dichromate (0.1 ml. 5% solution) added to the mercuric chloride solution did not influence the result, dichromate being reduced in the first step of Rupp's procedure.

These figures show that it is permissible to utilise the principles of Van Slyke's and of Rupp's methods without modification in devising a technique for the micro-determination of ketone-bodies. The accuracy attained is consistent with the requirements of tissue slice work.

*Specificity of the analytical methods.* The aniline and *o*-phenylenediamine citrate methods are specific for  $\beta$ -ketonic acids, but do not distinguish between acetoacetic acid and its higher homologues. Van Slyke's method is less specific for  $\beta$ -ketonic acids [cf. Peters and Van Slyke, 1932].

*Units.* The tissue metabolism is expressed by means of the following quotients:

$Q_{O_2} = \mu\text{l. oxygen uptake per mg. dry weight of tissue per hour.}$

$Q_{Acw} = \mu\text{l. CO}_2 \text{ acetoacetic acid (or } \beta\text{-ketonic acid) formed per mg. dry weight of tissue per hour.}$

1 millimol  $\beta$ -ketonic acid = 1 millimol  $\text{CO}_2$ .

$Q_{\beta\text{-Hydroxybutyric acid}} = \mu\text{l. CO}_2 \text{ } \beta\text{-hydroxybutyric acid formed per mg. dry weight of tissue per hour.}$

1 millimol  $\beta$ -hydroxybutyric acid = 1 millimol  $\text{CO}_2$ .

## EXPERIMENTAL.

*The ketogenic action of ammonium chloride in the absence of added substrate.*

The acetoacetic acid production of liver slices from young, well nourished rats is always increased two- to four-fold by an initial concentration of 0.04 *M*  $\text{NH}_4\text{Cl}$ , and generally there is a concomitant depression of respiratory activity. In older animals (12–24 months) the inhibition of respiration is not such a constant phenomenon, nor is the ketogenesis of such a high order, although it always occurs. These observations are illustrated in Table III.

Table III. *Ketogenesis in the absence of added substrate.*

Respiration and acetoacetic acid formation in rat liver slices surviving in phosphate saline containing ammonium chloride.

	No.	Without ammonium chloride		With ammonium chloride, 0.04 <i>M</i>		Method
		$Q_{O_2}$	$Q_{Acw}$	$Q_{O_2}$	$Q_{Acw}$	
Young rats 3–6 months	(1)	12.0	0.29	8.6	0.85	Aniline citrate
	(2)	13.9	0.45	11.0	1.02	"
	(3)	10.7	0.35	9.7	0.71	"
	(4)	11.1	0.23	9.8	0.64	<i>o</i> -Phenylenediamine citrate
	(5)	13.8	0.76	10.8	1.40	"
	(6)	13.1	0.59	9.5	1.38	Van Slyke (modified)
Older rats 12–24 months	(1)	9.4	0.42	10.4	0.61	Aniline citrate
	(2)	8.5	0.30	9.1	0.87	"
	(3)	9.4	0.16	8.5	0.52	"
	(4)	10.0	0.36	10.2	0.72	"

The three methods give results which are in good agreement. In a series of 30 observations the average  $Q_{Acw}$  for the controls was 0.38 (lowest 0.16 and highest 0.95), and with ammonium chloride 0.85 (limits, 0.47–1.40).

To some extent the magnitude of the ketogenesis is dependent on the concentration of ammonium chloride. Under the conditions employed a maximum effect is obtained with a concentration of approximately 0.05 *M*. Since the liver

removes ammonia rapidly—as much as 10  $\mu$ l. per mg. per hour [Krebs and Henseleit, 1932]—it is not surprising that ammonium chloride is effective only in high concentrations.

Table IV. *Influence of  $\text{NH}_4\text{Cl}$  concentration on ketogenesis in rat liver slices.*

0.005	0.32
0.014	0.43
0.04	0.95
0.20	0.00

Quite different is the response to ammonium chloride of liver slices from a rat which has been starved for 24 hours. The liver slices of a starved rat form large amounts of ketone-bodies (Table V(a)), but with such slices the ketogenic property of ammonium chloride is never seen in the absence of an added substrate; both respiration and acetoacetic acid production are partly inhibited (Table V(b)). Since the urea-forming capacity of the starved liver is below normal [Krebs and Henseleit, 1932], it is possible that the intracellular concentration of ammonia reaches and maintains a poisonous level.

Table V. *Ketogenesis in the absence of added substrate in the liver of the starved rat.*

- 12.1	2.44	0.04	- 7.6	1.74

The ketogenic property of ammonium chloride is not restricted to a phosphate saline medium. It occurs equally well in bicarbonate Ringer solution, where the respiration, as measured by the two-vessel method of Warburg, is normal or only slightly depressed. The respiration of liver slices always diminishes somewhat after one hour in phosphate saline, but when the medium contains

ammonium chloride the oxygen consumption falls off rapidly, until after 2 hours it is only two-thirds or even one-half of its initial value; whereas in bicarbonate Ringer solution there is a steadier respiration rate (Table VI).

Table VI. *Respiration and ketogenesis in the bicarbonate Ringer solution of Krebs and Henseleit [1932].*

*Ketogenesis in the presence of different substrates.*

A. *Fatty acids.* The sodium salts of the fatty acids were investigated with liver slices from well nourished rats and from animals which had been starved for 24 hours. The results of typical experiments are given in Table VII.

The table shows the following facts with regard to the well fed animal:

(1) All fatty acids, except formic and propionic, considerably increase acetoacetic ( $\beta$ -ketonic) acid production in the liver, the even-number fatty acids causing a greater increment than the odd-number acids (about three times as much). The results with the odd-number acids cannot be attributed to impurity, because the homogeneity of the specimens was tested by recrystallisation of the Ca salts.

(2) *n*-Hexanoic and *n*-octanoic acids yield ketonic acid at higher rates than butyric acid. This perhaps may be explained by assuming that the  $\beta$ -ketonic acid which is formed is not acetoacetic, but a higher homologue.

(3) Ammonium chloride increases the formation of acetoacetic ( $\beta$ -ketonic) acid from all fatty acids that yield ketone bodies. In the case of acetic acid a condensation to acetoacetic occurs, whereas with the other fatty acids the ketone-body arises by oxidation. Ammonia exercises its effect on both types of reaction.

In the starved rat the absolute figures for ketogenesis are higher, but ammonium chloride has no appreciable effect in most cases.

When the whole table is surveyed, it can be seen that the effect of ammonium chloride is to alter the metabolism of the well nourished liver in such a way that it approximates to the metabolism of the starving organ.

*Note.* It should be emphasised that the analytical methods used in this work do not distinguish between acetoacetic and other  $\beta$ -ketonic acids. No methods truly specific for acetoacetic acid are yet available. In the commentary the term "acetoacetic acid" has been used in accordance with custom, whereas " $\beta$ -ketonic acids" would be the more correct designation to apply to the products of oxidation of the higher fatty acids.

B. *Pyruvic, lactic and acetic acids.* The sodium salts of these acids were added to liver slices, and the results compared in the same way (Table VIII).

The influence of ammonia concentration on ketogenesis in the glycogen-poor liver has also been investigated in the presence of pyruvate and acetate (Table IX).

In the glycogen-rich liver the small ketogenic action of pyruvate was found to be materially increased by ammonia, whilst lactate, which is not ketogenic, was indifferent towards ammonia. In the starved liver, however, both acids were antiketogenic; despite this, pyruvate became ketogenic in the presence of ammonia. With acetate  $Q_{\text{O}_2}$  and  $Q_{\text{Acet.}}$  are reduced nearly 50% by concentrations of ammonium chloride varying from 0.04 to 0.0025M, but when pyruvic acid is the substrate, the respiration is not depressed and the acetoacetic acid formation increases with concentration of ammonia.

	Glycerol, 0.01 <i>M</i>	— 12.4	0.17	— 11.9	0.71

these only one—glycerol—proved efficacious. It had been observed previously that glycerol inhibited acetoacetic acid formation in starved liver slices to the extent of 80%. Monosaccharides, glycogen and ethyl alcohol failed to antagonise ammonia, whilst dihydroxyacetone and  $\alpha$ -glycerophosphate were ketogenic in themselves without addition of ammonium chloride. Here the possible intermediary is pyruvic acid. The details are shown in Table X.

*Interrelation of urea synthesis and acetoacetic acid formation.*

Since a relation was possible between urea synthesis and ketogenesis, the formation of ketone-bodies was studied under conditions in which the rate of urea synthesis was artificially raised by ornithine, with and without further addition of lactate. The ammonium chloride ketogenesis was diminished when the rate of urea synthesis was increased. The diminution may be caused by removal of ammonia (Table XI).

Table XI. *Urea synthesis and acetoacetic acid formation in the liver of a well fed rat.*

	(a) <i>With ornithine alone.</i>			Ammonium chloride, 0.04 M + ornithine, 0.02 M
	Control	Ammonium chloride, 0.04 M		
$Q_{O_2}$	-11.2	-11.8		-12.2
$Q_{Acac}$	0.25	0.70		0.50

$Q_{Acac}$	0.25	0.35	1.26		0.61
$Q_{Urea}$	0.38	0.36	2.14		5.04

*Note.* Urea is determined manometrically by the method of Krebs and Henseleit [1932], after the estimation of acetoacetic acid with *o*-phenylenediamine citrate. 0.1 ml. methyl red and 0.3 ml. 2 N NaOH are added to the mixed fluids in the Warburg vessel. The colour of the indicator is orange and the  $p_H$  about 5.0. Urea may then be determined in the usual way, acetate buffer being omitted, but the vessels must be filled with nitrogen to obviate an error due to autoxidation of *o*-phenylenediamine, which absorbs oxygen more rapidly in the presence of urease solution.

*Additional experiments relating to the cause of ammonium chloride ketogenesis—the keto-hydroxy ratio.*

It seemed possible that the point of action of ammonium chloride might be upon the keto-hydroxy-acid ratio. In this connection the effect of ammonia was examined in the presence of butyrate (Table XII).

Table XII. *Ketone-body formation in the presence of butyrate and ammonia.*

	Sodium butyrate, 0.01 M			
	Control	No substrate 0.04 M NH <sub>4</sub> Cl	Alone	0.04 M NH <sub>4</sub> Cl
$Q_{O_2}$	-13.0	-9.5	-16.9	-14.0
$Q_{Acac}$	0.59	1.38	2.85	3.95
$Q_{\beta\text{-Hydroxybutyric acid}}$	1.14	0.54	2.57	2.03

It appeared that ammonium chloride had moved the ratio slightly in favour of the ketonic acid. The experiments of Table XIII were performed to see if

Table XIII. *Effect of adding acetoacetic and  $\beta$ -hydroxybutyric acids.*

	Control	NH <sub>4</sub> Cl. 0.04 M. No sub- strate	Sodium aceto- acetate alone	Sodium aceto- acetate + 0.04 M NH <sub>4</sub> Cl	Sodium $\beta$ - hydroxy- butyrate alone	Sodium $\beta$ - hydroxy- butyrate + 0.04 M, NH <sub>4</sub> Cl
$Q_{O_2}$	-10.7	-9.3	-12.1	-10.8	-13.4	-11.5

Final amount found	27 $\mu$ l.	46 $\mu$ l.	163 $\mu$ l.	200 $\mu$ l.	183 $\mu$ l.	179 $\mu$ l.
Initial amount of $\beta$ - hydroxybutyrate (added)	Nil	Nil	Nil	Nil	224 $\mu$ l.	224 $\mu$ l.
Final amount found	19 $\mu$ l.	12 $\mu$ l.	123 $\mu$ l.	52 $\mu$ l.	95 $\mu$ l.	105 $\mu$ l.
$Q_{Acac}$	+0.51	+1.03	-1.61	-0.83	+4.72	+5.23
$Q_{\beta\text{-Hydroxybutyric acid}}$	+0.36	+0.27	+2.60	+1.19	-3.36	-3.47

All quantities of ketone-bodies are given in  $\mu$ l. CO<sub>2</sub>.

ammonium chloride influenced the reduction of acetoacetic acid and the oxidation of  $\beta$ -hydroxybutyric acid added to slices.

In the first place these experiments show an interconversion of the keto- and hydroxy-acids. Secondly they indicate that ammonium chloride has no significant effect on the reduction of acetoacetic acid or on the oxidation of  $\beta$ -hydroxybutyric acid.

*Effect of ammonium chloride on tissue respiration.*

When liver slices are permitted to survive in phosphate saline containing glucose and ammonium chloride, 0.01M, their behaviour presents a contrast to that of slices from other organs. Under the same conditions the respiration of brain and spleen is unaffected, that of kidney is increased and with testis and striped muscle there is little diminution of oxygen uptake; but the respiratory activity of liver slices frequently decreases by 20% or more. These effects are illustrated in Table XIV.

Table XIV. *Respiration of rat tissue slices in phosphate saline containing 0.014M glucose and 0.01M ammonium chloride.*

Tissue	Respiration	
	Glucose $Q_{O_2}$	Glucose + NH <sub>4</sub> Cl $Q_{O_2}$
Liver	-13.1	-10.1
"	-12.0	-8.6
"	-11.3	-10.7
"	-10.4	-9.5
"	-12.6	-10.4
"	-11.4	-9.2
Spleen	-11.0	-11.2
Brain	-14.5	-15.0
Diaphragm	-5.5	-4.7
Testis	-9.2	-8.3
Kidney	-22.6	-32.0

The respiration of the kidney was examined in the presence of other substrates (Table XV). In several instances there was an increase.

When the fate of ammonia was investigated, it was found that practically the whole of it was recoverable after the oxidation of glucose, showing that in this particular case ammonia increases respiration without being metabolised.

Table XV. *Respiration of rat kidney slices in the presence of ammonium chloride and of different substrates.*

Exp.	Substrate	Without NH <sub>4</sub> Cl Q <sub>O<sub>2</sub></sub>	With NH <sub>4</sub> Cl Q <sub>O<sub>2</sub></sub>	Initial concentration of NH <sub>4</sub> Cl M
1	Nil	- 19.3	- 14.4	0.008
	Glucose, 0.014 M	- 27.8	- 31.4	0.008
	Sodium acetoacetate, 0.005 M	- 24.8	- 15.6	0.008
2	Nil	- 16.6	- 14.2	0.008
	Glucose, 0.014 M	- 21.2	- 27.4	0.04
	"	—	- 24.8	0.01
	"	—	- 24.6	0.005
	"	—	- 23.3	0.002
	Glycerol, 0.01 M	- 21.7	25.9	0.008
	Fructose, 0.014 M	- 22.6	- 25.2	0.008
	Mannose, 0.014 M	- 18.2	- 26.3	0.008
	Galactose, 0.014 M	- 15.8	- 16.4	0.008
	Glycogen, 0.1 ml. 6%	- 19.4	- 19.7	0.008
	Pyruvate, 0.01 M	- 26.8	- 29.3	0.008
	Lactate, 0.01 M	- 30.9	- 47.0	0.04

Effects of ammonia on respiration have been reported previously. Warburg [1911] found that concentrations of free ammonia amounting to  $M/300$ – $M/1000$  increased the oxygen uptake of bird's erythrocytes surviving in serum or in saline; and Krebs [1932] has observed that the oxygen consumption of kidney slices to which ketonic acids have been added is increased by ammonium chloride.

*Ketone-body formation in organs other than liver.*

Quastel and Wheatley [1933] found no acetoacetic acid production in slices of brain and kidney. This has been confirmed, and the observations have been extended to spleen, testis and diaphragm. None of these organs forms measurable amounts of acetoacetic acid either in presence or in absence of ammonium chloride.

#### DISCUSSION.

The results of this work agree with Embden's perfusion experiments on fatty acid oxidation. It is clear from Embden's data [1906] that the ketogenic action of ammonia occurred in his experiments. When he neutralised a fatty acid with ammonia, he often obtained a greater production of acetoacetic acid than when he employed the sodium salt. Embden, however, drew no attention to the phenomenon.

Annau [1934] held the opinion that ammonium chloride exercised a ketogenic influence only on pyruvic acid. This is confirmed for the starved liver. In the well nourished liver the effect is observed not merely with pyruvic acid but with all the fatty acids, except formic and propionic, acetic showing the greatest increase.

#### SUMMARY.

1. Micro-methods for the determination of  $\beta$ -ketonic acids and of  $\beta$ -hydroxy-butyric acid are described. These are suitable for tissue slice work.
2. Annau's discovery that ammonium chloride increases the production of acetoacetic acid from pyruvic acid in liver has been confirmed.
3. In the absence of substrate ammonium chloride increases the production of acetoacetic acid in the well nourished liver but has no effect on starved liver,

where the rate of formation is already high. Ammonium chloride reduces the difference between the ketogenesis of the well nourished and of the starved liver.

4. The fatty acids, both those with an even number of carbon atoms and those with an odd number, give rise to  $\beta$ -ketonic acids during oxidation in liver slices. The even-numbered series yield about three times as much as the uneven series.

5. Ammonium chloride accelerates the formation of  $\beta$ -ketonic acids from most fatty acids in well nourished liver.

6. The effect of ammonia is inhibited by glycerol.

In conclusion I wish to acknowledge my great indebtedness to Dr H. A. Krebs, who suggested this investigation, and constantly gave his valued advice and criticism.

# CCXLVIII. THE EFFECT OF PARATHYROID HORMONE AND OF TUBERCULOSIS ON THE SERUM AND TISSUE CALCIUM OF GUINEA-PIGS

By GEOFFRY CHALLEN LINDER.

*From the Department of Pathology, University of Capetown.*

*(Received July 22nd, 1935.)*

EPISODES in the treatment of human tetany led Linder *et al.* [1930-31] to the conclusion that infection plays a large part in the success or failure of parathyroid extracts in raising the serum calcium and relieving the symptoms. When infection was present these extracts failed, and a similar effect of infection on the action of insulin is well established [Graham, 1924-25]. The experiments reported here were undertaken to study this and to investigate the effect of the parathyroid hormone on the distribution of calcium in the bone, brain and liver of normal guinea-pigs and of guinea-pigs infected with tubercle bacilli. An experimental clinical investigation was begun at the same time; the results showed that the nature of the infection was most important in influencing the response to injections of parathyroid hormone, typhoid fever decreasing it but pulmonary tuberculosis in its active stages increasing it [Linder, 1935].

## EXPERIMENTAL.

Young guinea-pigs weighing 150-200 g. were used. They were fed on bran, pollard and the outer leaves of cabbage. Four groups were studied; a control group, a group given injections of "Parathormone" (Eli Lilly and Co.), a group infected with tubercle bacilli by injection of a culture into the groin and a group similarly infected and treated with parathormone a month later when the infection was generalised. The dosage was 15 units the first day, 25 the second, 35 the third, 50 the fourth and the animal was killed the fifth day. The animals were not fed that morning and were killed by cutting the throat. The carotid blood was collected and the serum used for calcium determination. The humeri were removed, one being used for histology and the other being cut in two longitudinally, digested in pancreatic extract and 2% sodium carbonate to remove the marrow and bleached in dilute alkaline hydrogen peroxide. Absorption of the finer trabeculae was studied with a hand lens and graded by independent observers.

The livers of the parathormone-treated animals sometimes contained small pale areas which were removed for section; the cells showed degenerative changes but only in one instance was there histological evidence of calcification, and the calcium content of the remainder of this liver was not exceptional. The liver and brain, which were already drained of blood were weighed, mashed with a sharp knife, dried in an oven and ashed in small silica basins; the ashing was commenced over a low gas flame so that very little smoking occurred and was completed in an electric furnace at a dull red heat which was maintained for about 10 min. The ash contained a small amount of carbon. It was extracted

with about 2 ml. 50% hydrochloric acid on a water-bath for 15 min.; the acid was transferred to a graduated centrifuge-tube and the extraction was repeated with successive portions of dilute acid until the centrifuge-tubes contained 6 ml. in the case of the brains and 9 ml. in that of the livers. The contents of the tubes were mixed by inversion and the traces of carbon removed by centrifuging. 5 ml. of the brain extract and two 4 ml. samples of the liver extract were transferred to centrifuge-tubes for calcium determination. 1 ml. of saturated ammonium oxalate was added and then ammonia until the mixture was alkaline to methyl red; it was then reacidified with acetic acid and any phosphate precipitate redissolved. The tubes were capped and placed in boiling water until a definite cloud of calcium oxalate was seen. After standing for 24 hours the analysis was completed by the technique of Clark and Collip [1925].

### Results.

The results of the individual observations are given in Fig. 1, in which the mean value for each category is indicated by a horizontal line. These means of small samples have been compared by Fisher's [1930] method of the calculation

Fig. 1. Individual observations on the calcium content of serum, brain and liver of young fed guinea-pigs. Effect of parathyroid extract and of tuberculosis.

of  $t$ . The corresponding value of  $P$  was found from his Table of  $t$ . For the means to differ significantly  $P$  must be 0.05 or less. The means and the comparisons between them are given in Tables I-III.

*Sera* (Table I). The mean value of the serum calcium of the control guinea-pigs was 11.2 mg./100 ml. Bodansky *et al.* [1930] found a mean of 10.5 mg. After parathormone the mean was 12.0 mg. which just fails to be significantly greater than the mean of the controls; the value of  $t$  required for significance is 2.028

Table I. *Means of the series of serum calcium determinations and their statistical comparison.*

Series	Observations in series	Mean mg./100 ml.	Standard deviation	Mean deviation of mean	Compared with series	Difference of means mg./100 ml.	<i>t</i>	<i>P</i>
Control	29	11.18	1.01	0.187	—	—	—	—
Parathormone	8	12.01	1.13	0.400	Control	0.83	2.01	0.05 +
Tubercle	6	10.87	1.01	0.412	Control	0.31	0.69	Very large

Parathormone* (fasted)	3	15.23	1.51	0.872	Control	4.05	6.36	0.01

\* A series of animals given a single large dose in the fasting state.

and that obtained 2.01. A longer series would probably show a small real difference. A few observations made after a single dose of 50 units in fasting animals killed 24 hours after the injection gave a mean of 15 mg.; this greater and significant increase confirms observations of Bodansky *et al.* [1930]. Infection with tuberculosis did not alter the mean serum calcium, but parathormone acting on a tuberculous animal produced an increase which was significant in comparison with the means of the controls and of the tuberculous animals.

*Bone.* The bones showed definite absorption of the fine trabeculae in all the parathormone-treated animals. Tuberculous infection produced no change in the bones by itself, and did not appear to alter the extent of the absorption caused by parathormone. The histology did not show any specific tuberculous lesion in the bones.

*Brain* (Table II). The mean calcium content of the brains in the control series was 6.7 mg. per 100 g. fresh brain. The mean of the series treated with

Table II. *Means of series of brain calcium determination and their statistical comparison.*

mg. Ca per 100 g. fresh brain.								
Series	Observations in series	Mean	Standard deviation	Mean deviation of mean	Compared with series	Difference of means	<i>t</i>	<i>P</i>
Control	27	6.68	2.12	0.407	—	—	—	—
Parathormone	13	6.70	1.67	0.464	Control	0.02	—	—
Tubercle	7	5.47	0.843	0.318	Control	1.21	1.47	0.1 +
Tubercle and parathormone	7	7.11	1.71	0.645	Control	0.43	0.49	Very large
Tubercle	—	—	—	—	Tubercle and parathormone	1.64	2.29	0.05 —

parathormone was identical. The mean of the brains of the untreated tuberculous animals was lower, but the difference was not large enough to be significant; after parathormone these brains showed a significantly larger amount of calcium, but the increase was not sufficiently large to be real when compared with the normal controls. Parathormone therefore has no effect on the brain calcium under the conditions of these experiments with the possible exception of a small effect in the tuberculous animal.

*Liver* (Table III). The mean liver calcium in the control series was 4.2 mg. per 100 g. fresh tissue. This was definitely increased by parathormone and by tuberculous infection; the latter caused the greater increase. Tuberculosis increased the rise due to parathormone to a significant extent, but parathormone

Table III. *Means of series of liver calcium determinations and their statistical comparison.*

mg. Ca per 100 g. fresh liver.								
Series	Observations in series	Mean	Standard deviation	Mean deviation of mean	Compared with series	Difference of means	<i>t</i>	<i>P</i>
Control	23	4.17	1.025	0.213	—	—	—	—
Parathormone	7	5.21	0.852	0.321	Control	1.04	2.44	0.02
Tubercle	6	5.81	0.727	0.297	Control	1.64	3.69	0.01
Tubercle and parathormone	4	6.47	0.768	0.383	Control	2.30	4.25	0.01
Tubercle	—	—	—	—	Tubercle and parathormone	0.66	1.38	0.2
Parathormone	—	—	—	—	Tubercle and parathormone	1.26	2.43	0.05 -

did not increase the rise due to tuberculosis alone. Tubercle therefore seems the more potent agent. A solitary observation of 18.5 mg. was obtained after parathormone and this has not been included in the above data as it seemed likely that some other factor such as calcification must be operative.

#### DISCUSSION.

Bodansky *et al.* [1930] found a mean increase of 2.4 mg. in the serum calcium of young guinea-pigs from repeated doses of parathormone such as those given in the present experiments. Repeated doses of 10 units were without effect on the serum although slight absorption of bone was detected. Cohn and Stohr [1933] produced no effect on serum or bone with repeated doses of 1-5 units. Our results with the larger dosage showed but a questionable increase. The serum determinations in the tuberculous animals support the clinical observation that parathyroid hormone gives a greater response in an animal with an active tuberculous focus. The human cases were with one exception mild and the patients well nourished, but the guinea-pigs when exposed to the combined effects of tubercle and parathormone constantly lost weight, whereas they did so only occasionally and to a less extent when these agents were acting separately; so far as the animals were concerned it might have been that a starvation factor was operative in increasing the response as in the case of the fasting animal with the large single dose.

It is well known that the calcium content of the tissues is very different from one kind of animal to another, and that in the same kind of animal there is much greater individual variation than in the serum calcium. In any series, by one worker using one kind of animal under the same conditions, the highest figure is seldom less than three times the lowest. This applies to the present series and makes it difficult to demonstrate small changes caused by such an agent as parathormone. It is probable that in the tissue cells the calcium is present in protein-bound, diffusible and ionised components as it is in the serum. As it is believed that the ionised form is the most important in influencing cell activity, it is possible that variations in the amount of this fraction are buffered

by the presence of the protein-bound fraction, itself inactive and subject to considerable variation in amount.

In the following remarks the calcium figures quoted from the literature have been reduced to mg. per 100 g. of fresh tissue; to effect this the figures for the dry weight have been divided by 4.

Rona and Heubner [1919; Heubner and Rona, 1923] found that cat brain contained 8–17 mg. of calcium, and that this amount was not influenced by calcium therapy. Hess *et al.* [1932] found 25–65 mg. in rat brain and they quote dog and human brain as containing about 5 mg. and rabbit brain 125 mg. In rats with rickets the brain calcium was greatly reduced, but neither parathyroidectomy nor the injection of parathyroid extract influenced it. Underhill and Jaleski [1933] reported that 2–8 mg. was the titre in dogs and that parathyroidectomy had no effect. Eaves [1931] gave 4–6 mg. as the limits in four normal human brains but found pathological brains containing 8 mg. or more. The range of the present series is from 4.3 to 11.1 mg. with more observations in the lower half of the field, and no effect of parathormone was shown. Except for the changes reported in rickets by Hess the brain calcium seems resistant to external influences.

Heubner and Rona [1923] found 4–11 mg. of calcium in the liver of cats, and Dennis and Corley [1925] 7–11 mg. in rabbits; both failed to influence it by giving calcium salts. Underhill and Jaleski [1933] reported 1–3.5 mg. in dogs without change after parathyroidectomy. Barral and Barral [1928] found 0.3–6.8 mg. in rabbits. Ramage *et al.* [1933] found 6–40 mg. in the livers of sick children. Burns and Elliott [1935] found 0.5–2.5 mg. in the livers of guinea-pigs which had been bled and 3–5 mg. in the livers of those which had not; they found that pneumonia increased the liver calcium of rats from under 3 to as much as 10 mg. The observations presented here give the range of liver calcium in young guinea-pigs as 2.5–7.5 mg. per 100 g. fresh liver with a mean of 4.2 mg. and show that the liver calcium was increased by tuberculous infection and by parathormone. Both increases were small, but the two agents acted together to give a greater effect than either alone. Tuberculosis appeared to be the more potent.

The liver calcium appears more labile than the brain calcium but conditions under which the liver discharges calcium have not been found. The liver is probably not a calcium store of great quantitative importance, and unlike bone it seems to take up calcium under the influence of parathormone. This suggests that it may have a part to play in the finer regulation of the serum calcium, which would entail its taking up calcium when the serum calcium tends to rise.

The observations have added a few facts about the influence of tuberculous infection on parathyroid action, but the clinical results referred to at the commencement of this paper show that tuberculous infection was an unfortunate one to have chosen for the investigation of the general action of infections on the response to parathyroid hormone.

#### SUMMARY.

1. Injection of repeated large doses of parathyroid extract into a series of young guinea-pigs produced a mean increase of the serum calcium which was not quite large enough to be statistically significant.
2. Similar treatment of guinea-pigs which were infected with tubercle bacilli produced a larger mean response which was significant.
3. No difference could be detected in the degree of decalcification of bone caused by the parathormone in the two classes of animal.

4. Parathyroid extract had no effect on the calcium content of the brains of healthy guinea-pigs. It possibly increased the calcium in the brains of tuberculous animals.

5. The liver calcium was increased by parathyroid extract and by tuberculous infection. Tuberculous infection increased the response to parathyroid.

I wish to express my thanks to Prof. B. J. Ryrie for his help, to Dr E. C. Greenfield of the Department of Bacteriology for inoculating the animals and to Mrs Wylie for advice as to the statistical method to be applied.

# CCXLIX. THE RÔLE OF GLUTATHIONE IN MUSCLE GLYCOLYSIS.

By ROBERT GADDIE (*Beit Memorial Research Fellow*)  
AND CORBET PAGE STEWART.<sup>1</sup>

*From the Department of Medical Chemistry, University of Edinburgh.*

*(Received July 25th, 1935.)*

THE reactions by which carbohydrate is converted into lactic acid in muscle do not, according to the Embden-Meyerhof scheme, involve the intermediate production of methylglyoxal. The fundamental observation on which the exclusion of methylglyoxal is based is the production of lactic acid by dialysed muscle extracts to which magnesium ions and adenylypyrophosphate have been added. Such extracts are presumably free from glutathione [Meyerhof, 1933], and consequently contain no functioning glyoxalase. Meyerhof [1934] dismisses the fact that methylglyoxal has repeatedly been isolated from muscle extracts by assuming that in such cases it is either an artefact or a by-product formed spontaneously from triosephosphoric acids. It is known that in acid solution both synthetic glyceraldehydephosphoric acid and dihydroxyacetonephosphoric acid do yield methylglyoxal *in vitro* [Kiessling, 1934].

On the other hand it has been denied that methylglyoxal found in incubated muscle extracts is due to the presence of fixing agents [Auhagen and Aubagen, 1934]. The energy derived from the conversion of methylglyoxal into lactic acid has been shown to be utilised by cardiac muscle under anaerobic conditions [Gaddie and Stewart, 1934], and it therefore seems either that this reaction provides an alternative normal mode of breakdown of carbohydrate or that, even under anaerobic conditions, the muscle can use energy from abnormal reactions. According to Meyerhof's view of the position of methylglyoxal, glyoxalase must occupy a position analogous to that of catalase, except that in the latter case there is at least no evidence that the reaction catalysed serves any useful purpose other than the removal of a substance toxic when present in excessive amounts.

Even though the methylglyoxal be formed from its precursor without the intervention of enzymes, it cannot, on that account, be discarded as a by-product of no importance. The fact that the energy of its further breakdown to lactic acid is utilisable, in conjunction with the fact that it is formed under a variety of conditions, suggests that it is more than a by-product, and that, as has been suggested on several occasions [*e.g.* Gaddie and Stewart, 1934; Ashford, 1934; Jowett and Quastel, 1934], there exist alternative routes by which lactic acid may be formed from carbohydrate.

Recently we showed [Stewart *et al.*, 1934] that the Friedmann-Cotonio-Shaffer method for the estimation of lactic acid estimated methylglyoxal in addition, though other intermediates in carbohydrate breakdown did not interfere appreciably. We found that by distillation before removal of carbohydrate by copper sulphate and calcium hydroxide the methylglyoxal could be removed and the true lactic acid estimated in the residual solution. The interference of methylglyoxal has also been demonstrated by Giršavičius and Heyfetz [1934],

<sup>1</sup> In receipt of a part-time grant from the Medical Research Council.

who, however, removed the methylglyoxal by oxidation with hydrogen peroxide. Although Meyerhof and his collaborators had, presumably, used their manometric method for the determination of lactic acid, it seemed desirable to us to repeat the experiments with dialysed muscle extracts using the old and modified oxidation methods simultaneously, and to determine whether there was any marked accumulation of methylglyoxal in the absence of glutathione, and whether the presence of glutathione led to an increased production of lactic acid.

#### *Methods.*

We used, at first, a suspension in phosphate buffer ( $p_H$  7.5) of muscle dried *in vacuo* after repeated washing with acetone. The dried material was ground, suspended in water and dialysed through thin collodion membranes against running water for 8–12 hours. At this time no glutathione (or occasionally only a mere trace) could be detected in the fluid by the nitroprusside reaction, though the powder itself still gave a strong reaction owing to the presence of "fixed SH".

Later, we used a cell-free extract, prepared by freezing solid an aqueous suspension of the dried muscle powder and then centrifuging until the mass had thawed. The supernatant fluid was dialysed as before, but for a longer period—up to 16 hours. The shorter period was usually sufficient to yield a solution in which the nitroprusside reaction was negative.

Both frog and rabbit muscles were used, with essentially similar results. The experiments quoted in this paper were made with rabbit muscle.

Adenylpyrophosphate was added in the form of crude co-enzyme prepared from rabbit muscle as described by Lohmann [1931].

Lactic acid was estimated by the method of Friedemann, Cotonio and Shaffer, and by the modification described by Stewart *et al.* [1934]. In one or two experiments the distillate from the modified method was treated with 2:4-dinitrophenylhydrazine and shown to contain methylglyoxal.

#### RESULTS AND DISCUSSION.

The first question to be decided was of course whether the presence of glutathione had any effect on the production of lactic acid from glycogen. To answer this question the dialysed muscle extract, mixed with half its volume of phosphate buffer ( $p_H$  7.5), was activated by addition of glycogen, magnesium sulphate and adenylpyrophosphate. Reduced glutathione was added to an exactly similar mixture, and the extract with buffer and glycogen but no other addition was used as control. Air was excluded by a layer of paraffin and the reaction was allowed to continue overnight at room temperature.

Invariably the mixture containing glutathione yielded the most lactic acid and the control the least. The control was never absolutely negative, presumably owing to the difficulty of removing the last traces of glutathione and adenylpyrophosphate, but in most experiments it was very small. Its actual size depended *inter alia* upon the concentration of the muscle extract, but never masked the lactic acid production due to the presence of the co-enzymes. Comparison of the results obtained by using the old and modified forms of the method for lactic acid estimation showed (Table 1) that in the absence of glutathione, but not in its presence, there was a considerable accumulation of some substance which was not lactic acid but was estimated as such in the unmodified procedure. The results of Stewart *et al.* [1934] suggest that this substance was methylglyoxal. It was never isolated in these experiments, but

Table I.

Each mixture contained 20 ml. of dialysed muscle extract and 10 ml. of phosphate buffer,  $pH$  7.5, with the following additions: (a) substrate only, (b) as (a) + magnesium sulphate and adenylypyrophosphate, (c) as (b) + reduced glutathione.

Substrate	Lactic acid mg. per ml. of muscle extract	
	Original method	Modified method
Glycogen (a)	0.87	0.84
(b)	2.73	1.97
(c)	2.82	2.60
Glycogen (a)	0.36	0.23
(b)	2.00	0.83
(c)	1.81	1.23
Hexosediphosphoric acid (a)	0.32	0.31
(b)	0.77	0.39
(c)	1.56	1.44
Hexosediphosphoric acid (a)	0.42	0.41

(c)	1.03	1.00

was, on several occasions, distilled into a solution of 2:4-dinitrophenylhydrazine, and formed a red compound which gave the colour reactions characteristic of the methylglyoxal derivative. The presence of glutathione did not always completely prevent the accumulation of this substance, but it invariably decreased it markedly and sometimes abolished it. It seemed as though the rates of production and removal of methylglyoxal did not necessarily bear a constant relationship to one another in different preparations.

In all these experiments glycogen was the substrate. They indicate quite clearly that inactivation of the glyoxalase system by removal of glutathione causes a decrease in lactic acid production. Consequently they support the view that, in addition to the route suggested by Embden and Meyerhof, lactic acid may be formed from glycogen by way of methylglyoxal. Similar results were obtained with magnesium hexosediphosphate or glucose as substrate (Table I). Glucose and hexosediphosphoric acid resembled each other and differed from glycogen in giving increased activity in presence of glutathione as indicated by an increase in the apparent lactic acid determined by the unmodified method. With glycogen as substrate the unmodified method only occasionally indicated increased activity in the presence of reduced glutathione, and usually the results were similar to those shown in Table I. Geiger [1935], using the unmodified method, has recently reported results very similar to those which we have obtained by the same method of analysis and has concluded that reduced glutathione is without effect on the production of lactic acid from glycogen, but increases the lactic acid production from glucose. He thus suggests a qualitative difference between the mono- and poly-saccharides. Our results with the modified method of analysis show clearly that this conclusion is unjustified, and that the different behaviours of the two substrates are due to quantitative differences in the choice of alternative routes. It is of course possible that glucose does behave differently from glycogen, and that some glycogen is hydrolysed to glucose which is then converted, at least in part, by way of methylglyoxal into lactic acid, and that glycogen, *qua* glycogen, passes exclusively through the stages postulated by Embden and Meyerhof. The increased lactic acid production from glycogen in the presence of glutathione (and the accumulation of methylglyoxal in its absence) would then be explained

by hydrolysis of glycogen and hexosediphosphoric acid to glucose. Whether, in such a case, one describes the breakdown of glycogen to lactic acid by muscle as following two routes or only one, is really a matter of hair-splitting. This explanation however is less likely than that the difference between glycogen and glucose is merely quantitative, since the analytical differences are quantitative (as shown by application of the modified method) and since, moreover, hexosediphosphoric acid is an intermediate in the Embden-Meyerhof scheme for the production of lactic acid from glycogen and, by the unmodified method, gives results very like those given by glucose.

Our next object was to test Meyerhof's statement that any methylglyoxal formed in muscle preparations is an artefact or by-product. If this is the case, incubation of dialysed muscle extracts with glycogen and a magnesium salt alone should yield methylglyoxal, since this system is capable of forming triose-phosphoric acids [Meyerhof and Lohmann, 1934] which may then yield methylglyoxal spontaneously as they do *in vitro* in acid solution [Meyerhof, 1934]. Addition of reduced glutathione to such a system should then yield an equivalent amount of lactic acid. Experiments on these lines indicated (Table II) that the

Table II.

Each mixture contained 20 ml. of dialysed muscle extract and 10 ml. of phosphate buffer,  $p_H$  7.5, with the following additions: (a) glycogen, (b) as (a) + magnesium sulphate, (c) as (b) + reduced glutathione, (d) as (c) + adenylypyrophosphate.

	Lactic acid mg. per ml. of muscle extract

addition of magnesium alone to dialysed muscle extracts *plus* glycogen yielded only very small amounts of methylglyoxal, far smaller than those which were present in the more complete system containing adenylic acid pyrophosphate which we had previously studied. This at once suggested that the methylglyoxal which accumulated in the mixtures deficient only in glutathione had been produced by some process in which adenylypyrophosphate was concerned and which was therefore probably enzymic. When however glutathione was added to the mixture of dialysed muscle extract, glycogen and a magnesium salt, lactic acid was produced in quantities far greater than could be accounted for by the methylglyoxal produced in the absence of glutathione. The relatively small amount of methylglyoxal found in the absence of adenylypyrophosphate and glutathione negatives the supposition that formation of methylglyoxal had ceased owing to accumulation of that substance (a supposition hardly justified in any case if the reaction were non-enzymic), and that glutathione, by removing the excess of methylglyoxal, allowed its formation to continue. It therefore seems that glutathione, like adenylypyrophosphate, can, in some as yet unknown way, stimulate the production of methylglyoxal (see Table II). It is of course conceivable that glutathione, though not an essential component of the Embden-Meyerhof system, exercises an activating effect at one or more of the stages of

lactic acid production *via* pyruvic acid. Though there is no evidence to support this, there is equally none to refute it, and it remains a possible explanation of these results. It does not however affect the existence of an alternative route *via* methylglyoxal.

The last stage in the formation of lactic acid according to the Embden-Meyerhof scheme consists in the simultaneous reduction of pyruvic acid and oxidation of glycerophosphoric acid (to triosephosphoric acid). We have tested the influence of glutathione on this reaction. When magnesium ions and adenylypyrophosphate are added to the mixture of buffered dialysed muscle extract, sodium pyruvate and sodium glycerophosphate, lactic acid is formed, but the amount is considerably increased by the further addition of reduced glutathione. This is to be expected on the view that the triosephosphoric acid formed from glycerophosphoric acid may be transformed, in part at least, into methylglyoxal. The amount of extra lactic acid formed in presence of glutathione is quite considerable (Table III), and is definitely produced from the added substrate, but

Table III.

Each mixture contained 20 ml. of dialysed muscle extract, 10 ml. of phosphate buffer,  $pH$  7.5, equimolecular mixture of pyruvate and glycerophosphate, (a) alone, (b) + magnesium sulphate and adenylypyrophosphate, (c) as (b) + reduced glutathione. In each case a control without added substrate was used, and the values obtained from these controls have been subtracted to give the figures shown.

	Lactic acid mg. per ml. of muscle extract	
	Original method	Modified method
(a)	1.20	0.90
(b)	2.60	1.60
(c)	2.75	1.85
(a)	1.17	1.00
(b)	2.78	1.93
(c)	3.39	2.68

the quantitative examination of the results in detail is a matter of some difficulty since the controls may not be entirely adequate owing to the possibility of some carbohydrate remaining in the dialysed muscle extract. As controls we used dialysed muscle extract with the same additions of co-enzyme, glutathione *etc.*, and only the substrate mixture omitted, but even so, it is hardly fair to found any further conclusions on the basis of the exact amount of lactic acid produced.

In the early experiments on glycogen, the amounts of methylglyoxal which accumulated in the absence of glutathione varied considerably, and even in the presence of glutathione similar amounts occasionally remained. Since this suggested a difference in the rates of production and removal of methylglyoxal so that the time and conditions of incubation might seriously influence the results of analysis at the end of the experiment, we carried out a series of parallel experiments with and without glutathione, in which samples were periodically removed for analysis. Table IV gives the results of two such experiments. Throughout, the true lactic acid production was greater in the presence of glutathione than in its absence. A curious feature however was the early production of a large amount of methylglyoxal (or some substance which, like methylglyoxal, was estimated as lactic acid by the unmodified method but was removed by distillation), which later disappeared and was not accounted for as lactic acid. This phenomenon, of which we can offer no explanation, certainly

Table IV.

Each mixture contained dialysed muscle extract, buffer, glycogen, magnesium sulphate and adenylypyrophosphate. In addition, series B contained reduced glutathione.

24	2.00	1.81	0.83	1.23

helps to explain the variable methylglyoxal production which we had previously observed. It has been reported by Arayama [1934], who actually estimated the methylglyoxal, as its 2:4-dinitrophenylhydrazone.

#### SUMMARY.

Dialysed muscle extracts produce lactic acid from glycogen, glucose, hexose-diphosphoric acid or an equimolecular mixture of pyruvic and glycerophosphoric acids in greater amounts in the presence of magnesium ions, adenylypyrophosphate and reduced glutathione, than in the presence of the first two of these co-enzymes only.

In the absence of glutathione, methylglyoxal tends to accumulate; addition of glutathione diminishes and may prevent this accumulation.

In the absence of adenylypyrophosphate, magnesium ions and glutathione allow the production of lactic acid from glycogen by dialysed muscle extracts, but omission of the glutathione does not result in a corresponding accumulation of methylglyoxal.

During the formation of lactic acid, methylglyoxal accumulates and then disappears in part, the amount disappearing not being fully accounted for by conversion to lactic acid.

We have to thank the Moray Fund of this University for a grant which helped to defray the expenses of this work.

# CCL. THE RELATIVE CHOLINE-ESTERASE ACTIVITIES OF SERUM AND CORPUSCLES FROM THE BLOOD OF CERTAIN SPECIES.

BY EDGAR STEDMAN AND ELLEN STEDMAN.

*From the Department of Medical Chemistry, University of Edinburgh.*

*(Received July 16th, 1935.)*

FOLLOWING the discovery by Stedman *et al.* [1932] that the destruction of acetylcholine by blood serum was brought about by a specific enzyme, which they termed choline-esterase, Stedman *et al.* [1933] examined the blood sera from a number of species for the presence of this enzyme and compared the choline-esterase activities of these sera with their activities towards two other types of esters, namely, methyl butyrate and tributyrin. The results offered ample confirmation, if such were needed, of the specific nature of choline-esterase. It was further demonstrated that sera from different species differed widely with respect to their content of the enzyme in question, those from certain species being, in fact, so deficient in it that none was detectable by the method of estimation which was employed. It was, however, emphasised that the virtual absence of the enzyme from serum did not necessarily imply its absence from the corpuscles, the choline-esterase activities of which could not at the time be determined since the method of estimation used with serum was not applicable to whole blood or to corpuscles. In order to examine this point the present authors have therefore developed a method for the estimation of choline-esterase in corpuscles, defibrinated blood or tissue and have used it to determine the distribution of the enzyme between corpuscles and serum in the blood of a number of species. This work is described in the present communication. Since this investigation, which was reported to the Meeting of the Biochemical Society in Glasgow in June 1934, was completed papers have appeared on the same subject by Ammon [1934] and Ammon and Voss [1935] in which a method for the determination of choline-esterase is described which is identical in principle with that employed in the present work. Inasmuch, however, as Ammon employs a Warburg apparatus whereas we utilise the Barcroft differential apparatus our experimental procedure differs from that of the German workers. The material which we have examined is, moreover, by no means completely identical with that investigated by Ammon.

## *Estimation of choline-esterase.*

The method is an adaptation to choline-esterase of Rona and Lasnitzky's [1924] gasometric method for the determination of esterases, using, however, the Barcroft differential apparatus in place of Warburg's apparatus. The manometer is fitted with two flasks of the type described by Rona and Nicolai [1926] but of about 40 ml. capacity. In the actual estimation there are placed in each flask 5 ml. of bicarbonate Ringer's solution, prepared by mixing 100 ml. of 0.9% sodium chloride with 2 ml. of 1.2% potassium chloride, 2 ml. of 1.76% calcium chloride (calculated on the weight of the hydrated salt) and 20 ml. of 1.26% sodium bicarbonate, and 1 ml. of the liquid, or a weighed quantity of the solid, under investigation. Into the side-tube of one flask are then pipetted 0.5 ml. of the

bicarbonate Ringer's solution and 0.5 ml. of a solution of acetylcholine bromide of a concentration discussed below, the second flask being treated similarly except that water is used in place of the solution of acetylcholine. The apparatus is then assembled and partly immersed in a thermostat at 30°, leaving the stoppers of the side-tubes above the surface of the water. By removing the stoppers and attaching to the manometer, the stopcocks of which have been previously suitably adjusted, a reservoir containing a gaseous mixture composed of 95 % nitrogen and 5 % carbon dioxide, the flasks are swept out with this mixture, the stoppers are replaced, the stopcocks readjusted and the flasks immersed completely in the thermostat. Shaking is then commenced and continued until equilibrium is reached; the contents of the two compartments of the flasks are then mixed and readings of the manometer taken at definite intervals of time. Under the conditions chosen the rate of  $\text{CO}_2$  production is linear with time. It should be clear from this description that the determination depends upon the liberation of a molecule of carbon dioxide from the bicarbonate by each molecule of acetic acid produced by hydrolysis of acetylcholine. The gas mixture, containing 5 % of carbon dioxide, serves in conjunction with the bicarbonate as a buffer to maintain the  $p_{\text{H}}$  of the reaction mixture at 7.4. Determination of the constant of the apparatus, which represents the volume of carbon dioxide liberated under the atmospheric pressure obtaining at the time of the experiment but at a temperature of 0° for each unit difference, on an arbitrary scale, between the meniscus levels in the two limbs of the manometer, can be conveniently effected by means of a standard solution of acetic acid.

That the above method yields consistent results is shown by Table I, in which are recorded the results obtained, using four different apparatus, with one and the same purified solution of choline-esterase. The maximum deviation from

Table I. *Comparison of results using different apparatus.*

Apparatus number	Duration of experiment: 40 min.			Carbon dioxide at N.T.P. ml.
	Constant	Manometer reading	Bar mm.	
1	0.0477	4.18	740	0.194
2	0.0292	6.98	740	0.198
3	0.0470	4.34	740	0.199
4	0.0354	5.58	740	0.192

the mean value is only 1.5 %. But perhaps the best demonstration of the accuracy of the method is the comparison of the results which it yields with those obtained under similar conditions of temperature,  $p_{\text{H}}$  and substrate concentration by the titration method described in our earlier communication. Thus, using 1 ml. of an 80-fold dilution of a purified solution of choline-esterase, the following results were obtained by the manometric method in two experiments of 50 min. duration: App. 1a; const., 0.0374; reading, 3.65; bar., 744.5;  $\text{CO}_2$ , 0.134 ml. App. 2; const., 0.0292; reading, 4.88;  $\text{CO}_2$ , 0.140 ml. The mean volume of  $\text{CO}_2$  produced is thus 0.137 ml. In a titration experiment, using 20 times the amount of enzyme and of substrate in a solution of approximately 20 times the volume, 2.40 ml. of 0.02 *N* alkali were required to maintain the  $p_{\text{H}}$  of the solution at 7.4 during a period of 20 min. This would correspond with the liberation in 50 min. of 0.134 ml. of  $\text{CO}_2$  by the amount of enzyme used in the manometric experiments, which is in excellent agreement with the value actually found.

*Influence of substrate concentration on activity of enzyme.*

For the purpose of ascertaining the best substrate concentration to employ in the determination of choline-esterase by the above method, five solutions of different dilutions of acetylcholine were prepared as follows: solution no. 1, 5 g. acetylcholine bromide in 10 ml. of water; no. 2, solution no. 1 diluted with an equal volume of water; no. 3, solution no. 2 diluted with an equal volume of water; no. 4, 2 volumes of no. 2 diluted to 5 volumes; no. 5, 2 volumes of no. 2 diluted to 8 volumes. The non-enzymic hydrolysis of acetylcholine in these solutions, under the conditions defined above for the estimation of choline-esterase, was first determined, with the results shown in Table II. A comparison was then

Table II. *Non-enzymic hydrolysis of acetylcholine.*

Duration of experiment: 30 min.

Solution of acetylcholine no.	CO <sub>2</sub>
1	0.051
2	0.027
3	0.008
4	0.011
5	0.004

Table III. *Influence of substrate concentration on activity of choline-esterase.*

Duration of experiment: 30 min.

Solution of acetylcholine no.	CO <sub>2</sub>	CO <sub>2</sub> (corr.)
1	0.390	0.339
2	0.346	0.319
3	0.324	0.316
4	0.321	0.310
5	0.248	0.244

made of the carbon dioxide liberated according to the above procedure when 1 ml. of a purified solution of choline-esterase was employed as enzyme with 0.5 ml. of each of the above solutions as substrate. The results are recorded in Table III, the figures in the last column being corrected for non-enzymic hydrolysis. It is evident that the optimum substrate concentration has not been reached in these experiments. Nevertheless, at concentrations higher than that of solution no. 4 the rate of increase of enzymic activity with increase in substrate concentration is small. A solution of this concentration has therefore been adopted for use with the method of estimation here described. Apart from economising material, the employment of this solution in preference to one of higher concentration possesses the advantage that the non-enzymic hydrolysis is so small as to be almost negligible.

*Distribution of choline-esterase in normal human blood.*

The method described above has been used for measuring the relative choline esterase activities of human blood from a number of normal individuals. The results obtained are given in Table IV, the figures representing ml. of carbon dioxide evolved in 50 min. by the action of the choline-esterase present in 0.05

Table IV. *Distribution of choline-esterase in normal human blood.*

Subject number	Defibrinated blood	Serum	Corpuscles
1	0.377	0.353	0.198
2	0.268	0.148	0.179
3	0.256	0.126	0.195
4	0.244	0.133	0.184
5	0.243	0.138	0.165
6	0.232	0.144	0.156
7	0.213	0.111	0.146
8	0.199	0.115	0.126
9	0.198	0.084	0.141

ml. of blood or serum or in the corpuscles originally contained in 0.05 ml. of blood. Defibrination of the blood was effected by shaking with glass beads. The serum was obtained by centrifuging the defibrinated blood, whilst the corpuscles were washed twice with saline and then suspended in sufficient of this fluid to bring them to a volume equal to that of the blood in which they were originally contained. In each case 1 ml. of the material (defibrinated blood, serum or suspension of washed corpuscles) so obtained was dissolved in water and diluted to 20 ml., 1 ml. of the dilute solution being used in each estimation; the corpuscles were, of course, laked in this process. It should, perhaps, be mentioned here that if the dilution of the material to be examined is made with water, this should be done immediately prior to the actual estimation. Otherwise the choline-esterase activity of the material may diminish owing to the smaller stability of the enzyme in dilute solution.

*Distribution of choline-esterase in blood from other species.*

The choline-esterase contents of blood from a number of other species have also been examined. The relevant data are recorded in Table V. The technique of the estimations was identical with that used with human blood except that,

Table V. *Distribution of choline-esterase in blood from various species.*

Species	Defibrinated blood	Laked defibrinated blood	Serum	Corpuscles	Laked corpuscles
Horse	0.108	0.111	0.129	0.044	—
Guinea-pig	0.071	0.068	0.069	0.034	0.033
Ox	0.071	0.079	0.005	0.071	—
Pig	0.065	0.061	0.024	0.052	—
Sheep	0.037	0.039	0.004	0.036	—
Cat	0.023	0.022	0.035	0.0	—
Fowl	0.023	0.022	0.035	0.0	—
Duck	0.022	—	0.038	0.0	—
Rabbit	0.022	0.023	0.024	0.012	—
Goat	0.020	—	0.006	0.015	—

in most cases, a larger amount of material, frequently 1 ml., was used. This was necessitated by the smaller content of choline-esterase in the blood of these species. In order, however, to make the figures comparable with one another and also with those of Table IV they have been recalculated to correspond with the volume of carbon dioxide which would be evolved in 50 min. by the action of the choline-esterase present in 0.05 ml. of the material in question. It will be noted that, in some instances, estimations have been carried out both on laked and unlaked blood or corpuscles. Laking, in these cases, was effected either by dilution with water or by repeated freezing and thawing. It is quite evident from the figures that the choline-esterase activity of blood is in no way dependent on the presence of the intact corpuscles.

*Examination of cerebrospinal fluid and brain tissue.*

The application of the technique described above has so far been mainly confined to blood and has not yet been extended to a systematic investigation of various tissues for the presence of choline-esterase. An examination has, however, been made of cerebrospinal fluid and of brain tissue. In the former case no trace of the enzyme could be detected. Cerebrospinal fluid from two species, cat and man, has been examined both with the titration and gasometric methods. The results were entirely negative even when as much as 1 ml. of the material was

employed in the latter method. The brain, on the other hand, contains relatively large quantities of choline-esterase, the concentration in the basal ganglia being, in the cat, approximately twice that in the cortex. Thus, the basal ganglia and cortex from a cat's brain, which had been perfused with saline until completely free from blood,<sup>1</sup> were separately minced and examined by the gasometric method using, in each case, 0.25 g. of the tissue. Duplicate estimations were carried out, the following volumes of carbon dioxide being produced in a period of 15 min.: basal ganglia, 0.463, 0.448; cortex, 0.216, 0.204 ml.

#### SUMMARY AND DISCUSSION.

A method for the estimation of choline-esterase applicable to whole blood, corpuscles or tissue has been described and the results of its application to blood, cerebrospinal fluid and brain tissue recorded. The values obtained for the choline-esterase contents of blood sera from various species are in general agreement with those previously found by Stedman *et al.* [1933] using the titration method. Only in one case, namely, that of the cat, does any marked divergence appear between the results yielded by the two methods. This is no doubt due to the fact, exemplified by the results obtained with human blood, that considerable variations occur amongst individuals of a given species. In conformity with previous results, the blood sera from certain species (ox, sheep, goat) have been found to be, within the limits of experimental error, entirely deficient in choline-esterase. The corpuscles from these animals, however, are now shown by estimations both on defibrinated blood and on washed corpuscles to contain appreciable amounts of the enzyme in question. On the other hand the corpuscles from certain species (cat, fowl, duck) have proved to be devoid of any choline-esterase activity.

Choline-esterase is entirely absent from cerebrospinal fluid. Considerable quantities occur, however, in the brain, the concentration in the basal ganglia being approximately twice that in the cortex. This conforms with the findings of Dikshit [1934] that higher concentrations of acetylcholine or of an analogous substance are present in the former than in the latter material.

The expenses of this investigation have been partly met by grants from the Earl of Moray Research Fund of Edinburgh University.

<sup>1</sup> The authors desire to thank Dr B. B. Dikshit for preparing this material for them.

# CCL. SOME REMARKS CONCERNING THE NEW COLOUR REACTION OF VITAMIN A.

By EUGENE ROSENTHAL AND JOHN ERDÉLYI.

*From Budapest, Hungary.*

*(Received July 24th, 1935.)*

ANDERSEN AND LEVINE [1935] studied the new colour test of vitamin A described by us [1934, 1, 2] and came to the conclusion that the reaction takes the same course if the test-tube is simply warmed without the addition of catechol or guaiacol, and that therefore these substances are superfluous.

It is well known that the blue colour of the Carr-Price antimony trichloride test for vitamin A is not stable on standing, it slowly changes into violet, red, then yellowish red and finally becomes turbid. This colour change may be hastened by warming the test-tube, the shade of the warmed solution, however, differing from the colour which results when the colour change occurs without warming: a purplish hue is produced which subsequently turns into brick-red. This colour did not prove to be stable enough, and, in addition, the shade itself was found to be unsuitable for colorimetric comparison.

We therefore searched for substances capable of retarding or preventing this undesirable change of colour. Among the substances tried for this purpose at first catechol seemed to be the most suitable. In the course of spectrophotometric measurements, however, it soon became evident that the colour thus produced is not constant enough, as the maximum of its absorption is not stable (see Fig. 1). This change renders colorimetric estimation very difficult. Besides this, we found other drawbacks of the catechol method, which have been commented upon in a detailed manner in our second publication. We therefore made experiments with other phenols and their derivatives and found that guaiacol was the most appropriate for our purposes. The colour of the guaiacol test has been found extraordinarily stable and this has been verified by spectrophotometric measurements [Rosenthal and Weltner, 1935].

Thus guaiacol—and to a less extent catechol—has an inhibiting effect upon the reaction, as has also been stated by Andersen and Levine. In all our measurements we used washed absolute chloroform, as, according to our experience, water and alcohol have an unfavourable effect upon the reaction. The practice of Andersen and Levine of using chloroform not free from alcohol, therefore, cannot be endorsed.

As to carotene, it has been stressed also by us that the blue colour produced with antimony trichloride with the addition of catechol or guaiacol shows some

Fig. 1. Absorption curves of the new colour test for vitamin A performed with catechol: I, II, III, IV, absorption curves of the first, second, third and fourth 10-minute periods.

fading. This peculiarity of the reaction proved to be highly advantageous when the vitamin A content of blood had to be determined in the presence of carotene [Rosenthal and Szilárd, 1935]. The carotene content of blood, in the presence of catechol or guaiacol, does not give rise to a blue colour, whereas the pale violet-red colour yielded by vitamin A can be measured without difficulty.

We willingly agree with Andersen and Levine in that if we aim only at qualitative differentiation of vitamin A from carotene, the use of either catechol or guaiacol is superfluous; in this case, however, no warming is necessary either. The reaction mixture containing vitamin A will change its colour also if left to stand in the cold, whereas the blue shade of carotene produced by antimony trichloride is stable. Warming becomes necessary only if we wish to demonstrate vitamin A in the presence of carotene. However, as soon as our purpose is quantitative determination of vitamin A, in the interest of the possibility of exact colorimetric reading, the addition of guaiacol becomes advisable. The more so, as the shade produced without guaiacol is different from that given with added guaiacol. This has also been stated by Andersen and Levine. In the presence of guaiacol the colour is bluish and identical with that of a freshly prepared dilute solution of potassium permanganate. The wave-length of the typical absorption maximum of this colour exactly tallies with the wave-length of the yellowish green colour filter (No. 7) of the Leitz absolute colorimeter, which fact renders accurate measurements very easy.

It is on account of the facts mentioned that we recommend that the new colour test for vitamin A should be carried out with addition of guaiacol instead of by simply warming the test-tube.

## CCLII. SOME OBSERVATIONS ON THE ESTIMATION OF MUSCLE HAEMOGLOBIN.

By RODGER H. WATSON.<sup>1</sup>

*From the Biochemical Laboratory, Cambridge.*

*(Received July 25th, 1935.)*

NUMEROUS observations in the past decade, culminating in the isolation of the crystalline material and the study of its properties by Theorell [1932; 1934, 1, 2, 3, 4] have established the identity of muscle haemoglobin. Attempts to estimate it, however, have for the most part been concerned with it less as a chemical identity than as that haemoglobin which remains behind after perfusing the tissue apparently free of blood. The most notable of these is that of Whipple [1926]. Though his estimations show consistency, it is not certain that they represent the actual concentrations of muscle haemoglobin. There is the possibility that some haemoglobin has been lost in the perfusion of the tissue and uncertainty both as to whether there is an equal distribution of muscle haemoglobin between the tissue and the extracting fluid and as to the actual volume of the tissue. Further there is the possibility of other acid haematin compounds being extracted from the cell and introducing error into the subsequent acid haematin determination. Finally the conclusions drawn from the colorimetric comparison of the carboxy-compounds may be incorrect, for Theorell [1934, 2] has since shown that the light absorptions by the carboxy-haemoglobins of muscle and blood are different.

In this paper is reported an attempt to develop a method for a more exact estimation by extracting the whole of the haemoglobin from the unperfused tissue and by determining the relative concentrations of muscle and blood haemoglobin in the extract from the mean position of the  $\alpha$ -band of the oxy-haemoglobin compounds as observed with the Hartridge reversion spectroscope and the determination of the total concentration of haemoglobin spectrophotometrically. Some observations on Whipple's [1926] method of extraction, the outcome of a comparison of it with the method developed, are also reported.

Shenk *et al.* [1934] describe a method somewhat similar in principle. These authors are to be commended for their heroic effort in perfusing an ox. There exist, however, discrepancies between the spectrophotometric constants obtained with their extract of the perfused tissue and those obtained by Theorell [1934, 2] with the crystalline horse muscle haemoglobin. Though these may be due to the difference in the source of the haemoglobin, it has been the experience of the author that it is extremely difficult to perfuse a tissue entirely free of blood haemoglobin. Further, the same uncertainty as to the distribution of the haemoglobin between the tissue and the extracting fluid *etc.*, exists as in Whipple's [1926] method.

*Extraction of haemoglobin.* For the purpose of complete extraction, it was necessary that the muscle should be in as fine a state of division as possible. To this end, minced muscle ground with sand was employed. The tissue juices

<sup>1</sup> Senior Research Student of the Council for Scientific and Industrial Research of the Commonwealth of Australia.

slowly separate from minced muscle and sink towards the bottom of the mass. The tissue sample should therefore be weighed out immediately after mincing.

As Whipple [1926] found, water extracts the haemoglobin incompletely (see Table I). When the tissue was repeatedly extracted with *M*/15 phosphate buffer for periods of 3 hours, the fourth and subsequent extracts contained very little haemoglobin indeed, and after the fourth extraction no haemoglobin could be detected in the extracted tissue using the microspectroscope, the tissue being reduced to show strong cytochrome bands and then reoxidised until these had disappeared. On comparison of the acid haematin compounds of combined extracts 4 and 5 with those of combined extracts 1, 2 and 3 from a sheep heart muscle extraction, the former was found to be 2.4 % of the latter on one occasion and 4.5 % on another. It is considered that not more than 5 % of the total haemoglobin is left behind after repeating the extraction twice, if not more than 6 g. of tissue be used and the tissue be thoroughly ground with sand. The final solution becomes very dilute if the extraction is repeated further.

Whilst alkaline phosphate buffer will extract the haemoglobin completely, difficulty arises in the filtering, the filter tending to clog. In slightly acid phosphate buffer the extracts filter clear quite readily when shaken with kieselguhr and less readily, in fact rather slowly, with aluminium hydroxide. In acid solution, however, haemoglobin is absorbed by kieselguhr and aluminium hydroxide. It is readily washed off with alkaline solutions but, unfortunately, such solutions deflocculate the kieselguhr so that the washings are cloudy. These washings, however, when shaken with aluminium hydroxide, filter clear. Using a combination of kieselguhr and aluminium hydroxide, a crystal-clear filtrate may be obtained in a much shorter time than by using aluminium hydroxide alone.

That the adsorbed haemoglobin may be almost completely washed off was shown by shaking aliquots of a clear solution with further kieselguhr and aluminium hydroxide. With aluminium hydroxide the recoveries were 95 and 96 % in two cases tried. With kieselguhr, the apparent recoveries were 104 and 105 % owing to the faint cloudiness produced on washing with an alkaline solution. In both cases the amount of haemoglobin present was much less than in an ordinary determination.

For quantitative extraction, the following procedure, taking into account these various considerations, has been found a convenient one: 5–6 g. of well-minced muscle tissue are ground with an equal volume of sand. The well-ground mass is washed into a 25 ml. centrifuge-tube with 12–14 ml. *M*/15 phosphate buffer, about  $p_H$  6.5, and shaken gently for 3 hours. It is then centrifuged for 5 minutes at about 3000 r.p.m. and the supernatant liquor poured off and stored in the refrigerator. Another 12–14 ml. phosphate buffer is added, the tissue thoroughly stirred up with it and again extracted for 3 hours, after which the fluid is centrifuged off as before. This process is repeated a second time. The combined extracts are then centrifuged for 45 minutes and the supernatant liquor is poured off, shaken up with kieselguhr and filtered by suction, the filtrate being put through a second time after which it is usually crystal-clear, but, if not, it is put through still a third time. The residue on the filter-paper is washed with a few ml. of 0.1 % ammonium hydroxide till the washings which are collected separately are quite colourless. These washings are shaken with aluminium hydroxide and filtered afresh under gentle suction, this residue on the filter-paper also being washed with 0.1 % ammonium hydroxide. The extracts and washings are made up to 60 ml.

*Determination of the concentrations of muscle and blood haemoglobin relative to one another in a mixture of the two.* It having been established that the mean position of the  $\alpha$ -band of muscle oxyhaemoglobin is nearer the red end of the spectrum than that of blood oxyhaemoglobin, the mean position of the band in mixtures of the two oxyhaemoglobins suggested itself as a possible means of determining the relative concentrations of the haemoglobins in the mixtures. The nature of the relation between the mean position of the  $\alpha$ -band and the relative concentrations of the haemoglobins had to be determined.

Crystalline muscle haemoglobin of the horse was prepared after the method of Theorell [1932]. (It was redialysed twice, the crystalline mass being well washed each time with saturated ammonium sulphate solution.) It was taken up in phosphate buffer at  $p_H$  6.7. On the grounds of the observations of Roche [1932], the concentrations of the solutions relative to one another was obtained by colorimetric comparison of the acid haematins. To 7 ml. of solution 1 ml. of approximately  $N$  HCl was added and after 3 hours the acid haematins were compared colorimetrically. An excellent colour match was obtained. After storage of the haemoglobin solutions for 1 month in the refrigerator, the relative concentrations were still unaltered. Each of these solutions and various mixtures of the two were reduced with Stokes's reagent (alkaline ferrous tartrate) and reoxidised and the mean position of the  $\alpha$ -band determined with the Hartridge reversion spectroscope immediately. All readings were made at  $21^\circ$  and at the same concentration. They are plotted in Fig. 1.

Fig. 1. The relation between the % muscle oxyhaemoglobin in a mixture of muscle and blood oxyhaemoglobins and the mean position of the  $\alpha$ -band.

The observed position of the  $\alpha$ -band of crystalline muscle oxyhaemoglobin of the horse is  $5808 \text{ \AA}$ ,  $5 \text{ \AA}$ . nearer the red than was found by Roche [1932]. It is possible that Roche's solutions may have contained a little blood oxyhaemoglobin, but it is to be remarked that the observed value of the blood oxyhaemoglobin of the horse,  $5774\text{--}5 \text{ \AA}$ ., is  $5 \text{ \AA}$ . nearer the red than is reported by Barcroft [1928]. By comparison with the observations of Theorell [1934, 2], using the spectrophotometer, it would appear that the mean position of the  $\alpha$ -band differs somewhat from the position of its maximum absorption. As is evident from Fig. 1, this mean position of the  $\alpha$ -band changed uniformly throughout the

interval of 33–4 Å. as the relative concentrations of the oxyhaemoglobins to one another were changed.

It is, therefore, simple to obtain the relative concentrations of the haemoglobins in extracts of horse muscle tissue. They need only be brought to a temperature of about 20–21°, reduced with Stokes's reagent and reoxidised and the mean wave-length of the  $\alpha$ -band determined with the Hartridge reversion spectroscope immediately. The relative concentrations can then be read off from Fig. 1, the concentration of the solutions from which Fig. 1 was derived having been approximately the same as those found in extracts. The adjustment of the temperature is necessary in view of the observations of Hartridge [1923] that the mean position of the  $\alpha$ -band of oxyhaemoglobin changes with the temperature. A further necessary precaution is gentle treatment of the extract during reduction and reoxidation, as vigorous shaking produces cloudiness in the solution, a phenomenon reported by Douglas *et al.* [1912] for dilute haemoglobin solutions.

There is no reason to believe that a different relation will exist with the blood and muscle oxyhaemoglobins of other animals. Once then the mean positions of the  $\alpha$ -bands of these blood and muscle oxyhaemoglobins have been established, their concentrations relative to one another in tissue extracts can be determined.

*Spectrophotometric determination of the concentration of the total haemoglobins in extracts of muscle.* For this purpose the oxy-compound is unsuitable owing to the ease with which muscle oxyhaemoglobin changes into muscle methaemoglobin. The carbon monoxide compound of muscle haemoglobin can be used but, as Theorell [1934, 2] showed, it exhibits a relatively slight difference in its affinities for oxygen and carbon monoxide, so that the absence of oxygen must be ensured. As mentioned above, shaking, or for that matter any treatment which leads to the formation of bubbles, causes a precipitation of material. This, undesirable in itself, as being a direct source of spectrophotometric error, may to some extent cause loss of haemoglobin by denaturation.

The following procedure was applied: 10–15 ml. of the tissue extract were transferred to a large vacuum tube, sodium hydrosulphite added in certain excess of the amount necessary to remove all oxygen and the air replaced by coal gas or carbon monoxide. The vacuum tube was then gently rotated for a few minutes, after which a 1 ml. cell was completely filled with the carboxyhaemoglobin solution and quickly covered with a cover glass so that no air bubbles were retained. The spectrophotometer readings were made immediately at 6300, 5600 and 5400 Å.

The concentration of haemoglobin in the solution was calculated with the help of the formula

$$\epsilon = \frac{1}{cd} \log I_0/I,$$

where  $\epsilon$  is the specific extinction coefficient,  $c$  is g. of haemoglobin per litre of solution,  $d$  is the thickness of the spectrophotometric cell and  $I_0/I$  is the relation of incident to transmitted light.

The only outstanding figures for the specific extinction coefficients of muscle and blood carboxyhaemoglobins are those of the haemoglobins of the horse. At 5600 and 5400 Å. the specific extinction coefficients of crystalline horse muscle carboxyhaemoglobin are 0.55 and 0.71 respectively from the figures of Theorell [1934, 2] and of crystalline blood carboxyhaemoglobin 0.78 and 0.87 respectively from the figures of Haurowitz [1934]. It was assumed that these spectrophotometric constants of the carboxyhaemoglobins of the horse apply to the haemoglobins of the other domestic animals and that the specific extinction

coefficient of a mixture of muscle and blood carboxyhaemoglobins will vary between these values in direct linear relation with their relative concentrations in the mixture.

Having obtained the relative concentrations by means of the Hartridge reversion spectroscope, the specific extinction coefficient of the mixture could be calculated. The concentration of haemoglobin in the extract was then

$$\frac{\text{observed log } I_0/I}{10 \cdot \epsilon \text{ mixture} \cdot d} \text{ g./100 ml.,}$$

and in the tissue

$$\frac{\text{observed log } I_0/I \cdot v}{10 \cdot \epsilon \text{ mixture} \cdot d \cdot w} \text{ g./100 ml.,}$$

where  $v$  is the volume in ml. of the tissue extract and  $w$  the weight of the tissue sample in g.

The extinction at 6300 Å. was always appreciable, though according to Theorell [1934, 2] and Haurowitz [1934] it is negligible. In two or three cases where it was investigated, it was found that the absorption was general throughout the red, there being a slight gradual increase from 6800 to 6000 Å. As usually some faint opalescence was still present in the solution, it is considered that this absorption might have been due to it. In calculations, therefore, the values for  $\log I_0/I$  used were always the differences between  $\log I_0/I$  at 5600 or 5400 Å. and at 6300 Å., this being considered to be a nearer approximation to the true value. Appreciable absorption was found by Whipple [1926] in this region.

Roche [1932] having shown that the haematin of blood haemoglobin is identical with that of muscle haemoglobin, the experience gained in the course of the work indicates that the comparison of the acid haematin of the tissue extract with that of a blood standard may possess advantages over the spectrophotometric estimation. Excellent colour matches have been obtained between acid haematin solutions prepared from a solution of blood haemoglobin and from tissue extracts, indicating that neither the different globin nor the protein content of the extract affects the dispersion of the acid haematin appreciably. As mentioned in the introduction, however, there still remains the uncertainty as to the amount of haematin other than that of haemoglobin origin which is extracted from the tissue.

In Table I are presented the results of determinations made during the course of the work. The ox, sheep and pig hearts were obtained over a period of some months from animals at the slaughter house shortly after they were killed; the "shin beef" came from a dressed carcass; the dog heart and leg came from the one animal shortly after it was killed.

From the figures of Roche [1932], it would appear that the mean position of the  $\alpha$ -bands of the muscle oxyhaemoglobins of the horse, sheep, ox and dog are very nearly the same, whilst that of the muscle oxyhaemoglobin of the pig is some 4–5 Å. further towards the violet end of the spectrum. Observations on blood oxyhaemoglobin of the pig showed that the  $\alpha$ -band here too is some 5 Å. further towards the violet than is that of the oxyhaemoglobin of horse blood. On the basis of these observations, Fig. 1 has been applied directly in calculating the relative concentrations of the haemoglobins in extracts from ox, sheep and dog muscle and has been displaced 5 Å. in calculating them in extracts of pig muscle. The absolute concentrations reported are the mean of the figures obtained at 5600 and 5400 Å. The figures obtained at 5400 Å. were always higher than those at 5600 Å., the difference ranging from 3 to 15 %. This is probably due in part to the presence of methaemoglobin and in part to general absorption.

Table I. *Random observations on the concentration of haemoglobin in muscle.*

Tissue	Dry matter	Mean position of $\alpha$ -band in extract	% muscle Hb of total Hb	Conc. of total Hb, g./100 ml.	Conc. of muscle Hb, g./100 ml.
Ox heart	21.61	5800	76.5	0.80	0.62
		5798	70.5	0.77	0.55
Sheep heart	21.18	5789	45	0.66	0.30
		5790	48	0.67	0.32
Sheep heart	18.78	5790	48	0.51	0.25
		5790	48	0.53	0.25
		5797*	67.5*	0.35*	0.24*
Sheep heart	—	5788	42	—	—
Pig heart	21.75	5790.5	63	0.62	0.39
		5789.5	60	0.59	0.35
Pig heart	21.50	5785	46.5	0.74	0.34
		5786.5	51	0.70	0.36
Pig heart	20.45	5794	74	0.45	0.34
		5794.5	75	0.47	0.35
Dog heart	28.55	5788.5	43	0.52	0.23
		5789.5	46	0.51	0.23
Dog leg—gastrocnemius + soleus	25.72	5797.5	69	0.89	0.62
		5797.5	69	0.86	0.59
Shin beef	26.45	5806	94	0.67	0.63
		5806	94	0.71	0.67
Shin beef	—	5805	91	—	—

\* Extracted with distilled water.

The difference in the relative concentrations of blood and muscle haemoglobin in heart and skeletal muscle was unexpected. The "shin beef" (Table I) was obtained after the carcass had been dressed. Under similar conditions Shenk *et al.* [1934] have found that 90–100% of the haemoglobin of the "rib-eye" muscle of the ox is muscle haemoglobin.

The high relative concentration of muscle haemoglobin in skeletal muscle is a fact to be borne in mind in the study of the colour of meat. The actual concentration of muscle haemoglobin found by Shenk *et al.* in the "rib-eye" muscle was 0.30–0.45% of the tissue, though the values are probably somewhat low as water was used as extractant. The extensive figures of Whipple [1926] show an apparent normal concentration of 0.3–0.5% muscle haemoglobin in the heart muscle and 0.6–0.8% in the gastrocnemius muscle of the dog. As mentioned in the introduction and further discussed below, it is also somewhat doubtful exactly how close these figures are.

*Some observations on Whipple's method of extraction.* A sample of tissue was extracted with 0.1% ammonium hydroxide according to the procedure of Whipple [1926]. An absolutely clear filtrate was obtained only after filtering under gravity with a little aluminium hydroxide. At this alkaline reaction there is very little absorption of haemoglobin. 5 ml. of the haemoglobin extract thus obtained were diluted with 5 ml. of water, 2 ml. of approximately *N* HCl added and the solution set aside in the refrigerator. A standard blood acid haematin solution was simultaneously prepared and similarly treated. These acid haematin solutions were colorimetrically compared after 20–24 hours.

Another sample of the tissue was extracted according to the method described above. To 15 ml. of the extract, 2 ml. of approximately *N* HCl were added and,

after 24 hours in the refrigerator, the resulting acid haematin solution was also compared with a simultaneously prepared solution of the blood acid haematin standard. The following are the results:

Concentration in tissue: Whipple's method	...	...	...	13.42x
Concentration in tissue: method of complete extraction	...	...	...	10.55x

where  $x$  was the concentration of haemoglobin in the blood solution from which the acid haematin standard was prepared.

Calvo-Criado [1925] has shown that muscle tissue extract causes the breakdown of haemoglobin. Whilst such a breakdown might account for some of this unexpected difference between the results if the velocity of the breakdown were different in the two solutions, almost the whole difference has been traced to another source, that of the unconsidered volume of the tissue in Whipple's method of extraction which becomes considerable owing to the imbibition of fluid. This was shown in the following manner. Approximately 10 g. of sheep heart muscle tissue were made up to 50 ml. with 0.1 % ammonium hydroxide and set aside in the refrigerator at 2–4° for 20–24 hours. The mixture was then centrifuged and a known volume of the supernatant fluid pipetted off and filtered clear. The removed haemoglobin solution was replaced by the same volume of 0.1 % ammonium hydroxide, the mixture set aside in the refrigerator for a further 20–24 hours, centrifuged and the supernatant fluid filtered clear. The densities of the colour in the two solutions were then compared. From the ratio of the colour densities, it needs but a simple calculation to arrive at the volume of the tissue. The results obtained were

Weight of tissue in g.	Volume in ml.	Volume %
8.4	11.5	23.0
8.4	12.6	25.2
10	12.8	25.6
10	14.1	28.2

\* Some of the same sample with which the comparison of the two methods was made.

That imbibition of fluid by the tissue has occurred is apparent, for after centrifuging barely 30 ml. of supernatant fluid were present. It would thus appear that the results given by Whipple's method are somewhat high. It is perhaps of interest that throughout crystal-clear filtrates could only be obtained with the greatest difficulty when Whipple's method of extraction was employed.

#### SUMMARY.

1. The total haemoglobins of mammalian muscle have been estimated by a spectrophotometric method, and a convenient method of quantitative extraction from well-ground muscle is described.
2. The relative concentrations of blood and muscle haemoglobins in a solution can be determined by the Hartridge reversion spectroscope. The muscle haemoglobin can then be estimated in muscle containing blood.
3. The colorimetric method of estimating haemoglobin by conversion into acid haematin was found suitable for the muscle extract.
4. The method of quantitative extraction gives results about 30 % lower than the method of Whipple [1926].
5. A small number of estimations of muscle haemoglobin, chiefly in heart muscle, are reported. Less muscle haemoglobin was found in the bullock's heart than in shin beef.

In acknowledgement, it may be mentioned that Mr J. Hammond, who was interested in the part muscle haemoglobin might play in the colour of meat, suggested this work. Mr R. Hill throughout gave me the benefit of his experience and I am greatly indebted to him for his interest and advice.

# CCLIII. THE ASSAY OF FAT-SOLUBLE ANDROSTERONE-DIOL.

BY VLADIMIR KORENCHEVSKY AND MARJORIE DENNISON.

*From the Lister Institute.*

*(Received July 24th, 1935.)*

THIS paper is a continuation of the investigation which was started at the request of Prof. Ruzicka in order to study the physiological and possible pathological properties of his preparations of male sexual hormones.

Tscherning as reported by Butenandt [1934] and Ruzicka *et al.* [1935] prepared a diol ( $C_{19}H_{32}O_2$ ) from androsterone. The activity of this substance on the comb growth of capons was about three times that of androsterone. From Tschopp's experiments [Ruzicka *et al.* 1935, p. 213] one capon unit was found to be contained in about 15–20γ of diol (6 days of injection, Tschopp's method), or in 50–60γ (2 days of injection, Butenandt's method), or in 33γ by Callow and Deanesly [1935]. The following experiments give the result of the assay on castrated rats of this diol received from Ruzicka.

## *Technique.*

We shall call this diol preparation which is soluble in fat solvents and in oil "fat-soluble diol" in order to distinguish it from the esters of diol from which it is possible to prepare watery solutions.

The experiments were performed on 49 rats belonging to 10 litters. The number of rats, their age and average final weights are given in Table I.

Table I. *Fat-soluble diol.*

Number of rats in each litter. Age and average final weights of rats (g.) in each group of each litter.

No. of litter	No. of rats in litter	Age at castra- tion days	No. of days after castra- tion injection started	Control rats	Weights of rats				
					Rats injected with $\gamma$				
					25	50	100	200	350

The solution of diol in olive oil was prepared in the same way as the solution of androsterone [Korenchevsky and Dennison, 1935]. We found that even with a 0.2% solution of diol in oil a few crystals were deposited on standing after the ampoules had been opened and part of the solution used. Therefore the

highest concentration used in our assay was 0.175 % (350 $\gamma$  in 0.2 ml. daily) at which concentration no crystals could be detected in the solution, even when kept for a considerable time.

*Effect on the seminal vesicles, prostate and prostate with seminal vesicles.*

As can be seen from Tables II and III and Figs. 1 and 2 the effect was considerably greater on the seminal vesicles than on the prostate. Therefore the weight of the prostate and seminal vesicles together showed a larger effect than that given by the prostate alone (Table V, Fig. 3). There was no very definite difference between the results obtained from the actual weights and the weights per unit of body weight.

Table II. *Influence of fat-soluble diol on seminal vesicles.*

*The rat unit of diol.* In agreement with our definition [Korenchevsky and Dennison, 1934, p. 1498], since 25 $\gamma$  produced 48 % increase in the actual weight of the prostate and 44 % increase in the weight per unit of body weight, one rat unit of "comb growth activity" is contained on the average in about 21 $\gamma$ , whilst, since 25 $\gamma$  produced about 53 % increase in the actual weight of the prostate with seminal vesicles and 51 % increase in the weight per unit of body weight, one rat unit of "whole male sexual activity" is contained in about 19 $\gamma$ .

These two values for diol are close to the value of the capon unit (15–20 $\gamma$ ) given by the experiments of Tschopp, mentioned above, in which diol was injected for 6 days, but are about one-third of that given by Butenandt's method (2 days of injection, 50–60 $\gamma$  per capon unit).

Direct experiments using these doses of 19 and 21 $\gamma$  were not carried out, as the curves for the prostate (Figs. 1 and 2) show that a linear relationship between the dose and the percentage increase may be assumed for the range 0–50 $\gamma$ .

It is clear from Tables II and III that the value of the rat unit is different for different doses injected in solutions of different concentration, the higher

doses producing effects, which are not directly proportional, the increase in the effect being less than the corresponding increase in the dose. This relation may be shown in the following way. If, instead of defining the rat unit as the minimum dose producing a 40% increase in the weight of the prostate (as required by our method of assay), it were defined as the proportion of any dose giving such an increase, then the number of rat units injected for the doses used would be as follows: 25 $\gamma$ , 1.2 R.U.; 50 $\gamma$ , 2.2 R.U.; 100 $\gamma$ , 2.9 R.U.; 200 $\gamma$ , 4.4 R.U.; 350 $\gamma$ , 5 R.U.; or, on the basis of these calculations, one rat unit would appear to be contained in 21, 23, 34, 45 and 70 $\gamma$  respectively.

In order to explain the different effects of different concentrations, it will be necessary to inject different doses with a solution of a fixed concentration.

Fig. 1. Relation between dose of fat-soluble diol and % increase in actual weight of prostate and of seminal vesicles.

Fig. 2. Relation between dose of fat-soluble diol and % increase in weight per unit body weight of prostate and of seminal vesicles.

*Effect on the penis and preputial glands.*

As can be seen from the figures of Tables IV and V the effect of diol on the penis was much more regular and comparatively greater than on the preputial

Fig. 4. Relation between dose of fat-soluble diol and % increase in actual weight of penis.

Fig. 5. Relation between dose of fat-soluble diol and % increase in weight per unit body weight of penis.

glands, on which the smaller doses had no constant (25  $\gamma$ ) or considerable (50  $\gamma$ ) effect.

The curves obtained for the effect on the penis (Figs. 4 and 5) fit all the results obtained closely.

*Effect on the fat deposition, the adrenals, the thyroid and the thymus.*

It is difficult to attach a definite significance to the effect on these organs, since the changes were small and only occurred in some cases. Since, however, in the majority of rats the injections caused a decrease (per unit of body weight) in the weight of the adrenals (5–34 %) and of the thymus (3–26 %) it can be said that the effect was typical of a return towards normal in these organs.

*Statistical description of the curves.*

J. M. C. Scott, under supervision of Prof. E. S. Pearson (Department of Statistics, University College), has represented graphically in the form of the above curves the results of the assay.

"The curves are approximately rectangular hyperbolas through the origin

$$y = \frac{bx}{x+a}.$$

These curves contain two adjustable constants  $a$  and  $b$ , but it is not easy to determine them by least squares. In practice therefore a curve

$$y = \frac{bx}{x+a} + \frac{cx^2}{(x+a)^2}$$

was constructed, where  $a$  was chosen beforehand and  $b$  and  $c$  were found by least squares. It can be proved that, if  $a$  is fairly near the correct value, the effect of the additional term is almost exactly equivalent to that of adjusting  $a$ , but the procedure is now the much simpler one of fitting a quadratic."

DISCUSSION.

In Table VI, the data obtained in our previous experiments on androsterone [Korenchevsky and Dennison, 1935] are compared with the corresponding data of the effects of diol on the sexual organs.

Table VI. *Comparison of the effect of fat-soluble androsterone with that of fat-soluble diol.*

Organs	Weights	I	II	III	IV
		Average % increase per 100 $\gamma$ for doses			
		200-900 $\gamma$ androsterone	25-200 $\gamma$ diol	200 $\gamma$ androsterone	200 $\gamma$ diol
Seminal vesicles	{ Actual	23.0	223	19	150
	{ Per unit of body weight	22.6	216	14	143
Prostate	{ Actual	24.7	144	24	88
	{ Per unit of body weight	23.7	135	20	83
Prostate with seminal vesicles	{ Actual	24.3	156	23	98
	{ Per unit of body weight	23.3	149	18	93
Penis	{ Actual	11.0	100	14	51
	{ Per unit of body weight	10.3	93	9	42
Preputial glands	{ Actual	18.0	37	29	39
	{ Per unit of body weight	18.0	33	23	34

In making the comparison the average percentage increase in the weight of the organs per 100 $\gamma$  was chosen, using for both hormones those parts of the curves before the beginning of the pronounced flattening, *i.e.* for androsterone, the average percentage increase obtained after the injection of doses from 200 to 900 $\gamma$  (column I) and for diol of doses from 25 to 200 $\gamma$  (column II). In addition a comparison was made of the effects of the dose of 200 $\gamma$ , which was used in both the androsterone and diol experiments (columns III and IV).

It is clear that the two substances differ considerably. The effect of diol on all the secondary sexual organs is much more powerful than that of androsterone. Thus the effect of diol on the seminal vesicles is about 8–10 times stronger than that of androsterone; on the prostate about 4–6 times and on the penis about 4 times with the higher doses and 9 times with the calculated average dose. The effect of diol on the preputial glands is about twice that of androsterone.

This difference is also shown by the comparison of the rat units of androsterone (170 $\gamma$ ) and diol (about 21 $\gamma$ , *i.e.* 8 times greater).

Whilst the effect of androsterone on the seminal vesicles is about the same as or a little less than that on the prostate, in the case of diol the former glands are stimulated more than the latter.

A similar effect was also noted by Callow and Deanesly [1935], who, simultaneously with ourselves, carried out experiments using the principle of investigation advocated by us, *i.e.* judging the effect by changes in the weights of the organs fixed in Bouin's solution.

A comparison of the curves of increase in the weight of prostate in the androsterone assay [Korenchevsky and Dennison, 1935] and the diol assay shows a further difference—that, whilst the effect of androsterone is directly proportional to the dose within a comparatively large range of doses, this is not the case with diol.

In capons the effect of diol was found to be three times stronger than that of androsterone. In our present experiments the effect was found to be about eight times greater than that of androsterone. The data mentioned above indicate the importance of making the assay on mammals, in particular on rats, since it seems to be easier to differentiate between diol and androsterone on rats than on capons. For this purpose (*a*) the great difference in the values of the rat units and (*b*) the great difference in the effects on the seminal vesicles should be used.

#### SUMMARY.

1. Pure crystalline androsterone-diol prepared by Ruzicka was dissolved in olive oil and assayed by the authors' method on 49 rats belonging to 10 litters, the results being graphically represented by the curves for the prostate, seminal vesicles and penis.

2. One rat unit of "comb-growth activity" was found to be contained in less than 25 $\gamma$ , in about 21 $\gamma$ , whilst one rat unit of "whole male sexual activity" was contained in about 19 $\gamma$ .

3. Thus, whilst on capons diol was found to be about three times stronger than androsterone, using castrated rats its activity was found to be about eight times that of androsterone.

4. In the assay of these two hormone preparations two features differentiate diol from androsterone: (1) the greater activity of diol as expressed by the rat unit and (2) its action in stimulating the growth of the seminal vesicles more than that of the prostate.

5. The effect of diol on the penis and on the preputial glands is also greater than that of androsterone, the reaction of the penis being more pronounced and regular than that of the preputial glands.

Grants from the Lister Institute and from the Medical Research Council have enabled us to carry out this work and to them our thanks are due. We are much indebted to Prof. E. S. Pearson, Mr J. M. C. Scott and the Department of Statistics of University College for the statistical investigation of the results obtained. We would also like to thank Messrs Ciba, Ltd., for supplying the material and Mr T. F. Smart for his assistance in obtaining this material.

# CCLIV. THE EFFECTS OF WATER-SOLUBLE PREPARATIONS OF ANDROSTERONE AND ANDROSTERONE-DIOL ON CASTRATED RATS.

BY VLADIMIR KORENCHESKY, MARJORIE DENNISON  
AND SAMUEL LEVY SIMPSON.

*From the Lister Institute, London.*

*(Received July 24th, 1935.)*

RUZICKA *et al.* [1935] prepared a monosuccinic ester of androsterone, of which Prof. Ruzicka sent to us two water-soluble preparations for investigation: (1) the sodium salt and (2) the lithium salt. In the following they will be designated as "w.-s. androsterone". We also received from Prof. Ruzicka a lithium salt of the monosuccinic ester of androsterone-diol, which will be designated as "w.-s. diol."

Tschopp [Ruzicka *et al.*, 1935, p. 213], using his method of injecting capons once a day for 6 days, found that 1 c.u. was contained in 80–100 $\gamma$  of w.-s. androsterone and (according to a personal communication) in about 200 $\gamma$  of w.-s. diol.

As in our preliminary experiments the activity of w.-s. diol on castrated rats was found to be much greater than that of w.-s. androsterone, most of the experiments were performed with the diol salt; some of the experiments were carried out with the lithium salt of w.-s. androsterone. The results of these experiments are given in the present paper.

## *Technique.*

The salts were received in solutions of known strength. They were distributed in ampoules and steamed for 30 min. on 3 consecutive days. Dilutions were prepared with distilled water, which in some preparations caused opalescence and the formation of a small amount of precipitate; this however did not interfere with the accuracy of the test. Before taking the solution into the syringe, care was taken to suspend the precipitate in the solution by stirring it well.

The solutions were injected into the animals in quantities of 0.1–0.2 ml. per injection, each 0.1 ml. being injected into a separate place under the skin.

Whilst in our experiments oily solutions were always injected twice daily, the water-soluble preparations were injected three times daily, between 9.30 and 10 a.m., at 3 p.m. and between 9 and 11 p.m. This was done because it is well known that water-soluble hormones are usually quickly absorbed from the subcutaneous tissue and quickly excreted or perhaps inactivated in the organism.

Since, in our previous papers on assays, we have given a sufficient number of details in the form of tables, some of the detailed tables are omitted from this paper in order to economise space.

Fig. 1. Relation between dose of water-soluble diol and percentage increase in actual weight of prostate and of seminal vesicles.

Fig. 2. Relation between dose of water-soluble diol and percentage increase in weight per unit body weight of prostate and of seminal vesicles.

## I. Water-soluble diol.

*Assay.* Experiments were performed on 71 rats, belonging to 13 litters, castrated 21–26 days after birth.

Seven days of injection were started 30–38 days after castration. The weights of the rats varied comparatively little, being between 183 and 234 g. at the end of the experiment. Daily doses of 97, 194, 389, 777, 1555 and 3109 $\gamma$  were injected, the total number of rats in each of the groups injected with these doses being 10, 6, 9, 8, 9 and 4 respectively. The total number of control rats was 25. The technique of assay was the same as that used in the previous paper.

*Effect on the secondary sexual organs.* w.-s. diol had a considerably greater effect on the seminal vesicles than on the prostate as is shown by Tables I and II

Table I. Influence of w.-s. diol on seminal vesicles.

The average weights, actual and calculated per 200 g. of body weight, of the seminal vesicles of the rats in each group of each litter and their percentage increase after the injections.

and Figs. 1 and 2. Therefore the effect on the prostate with seminal vesicles was also greater than that on the prostate alone (Table III, Fig. 3). The action on the penis and preputial glands was much less (Tables III and IV). The penis however gave a comparatively regular response to the different doses (see Figs. 4 and 5), whilst in the case of the preputial glands there was no such regularity.

*The rat unit.* Taking that part of the curve of the average percentage increase in the weight of the prostate between 0 and 194 $\gamma$  to be a straight line, 40% increase, i.e. one rat unit of "comb-growth activity" would be contained in

about 67%. The rat unit of the "whole male sexual activity" (40% increase in the weight of the prostate with seminal vesicles) would be contained in about 64%. These amounts of the water-soluble salt contain about 50 and 48% of pure diol respectively.

*Effect on the other organs and tissues.* Changes of less than 10% in the weights of the organs were not taken into consideration. There was no change in the gain in body weight during the period of the injections. Of the 14 groups injected there was a slight increase in the fat deposition in 10, as judged by the increase in weight of the intra-abdominal fat (13–66%). In most groups (9 out of 14) the adrenals decreased slightly (11–36%) and thyroid increased slightly (10–52% in 8 out of 14 groups). There was also a decrease in the weight of the thymus in most groups (13–38% in 9 groups).

Fig. 4. Relation between dose of water-soluble diol and percentage increase in actual weight of penis.

Fig. 5. Relation between dose of water-soluble diol and percentage increase in weight per unit of body weight of penis.

The hypophysis was examined in only six litters and in five of the litters the hypophysis of the rats injected with diol decreased by 10–27 %.

Although all the changes which have been mentioned above were small and not invariably present, the direction of the changes was specific for the respective organs of castrated rats, in which the injection of testicular hormone is causing a return towards the normal condition.

No changes were found in the weight of the liver, kidneys, spleen or heart.

## II. Water-soluble androsterone.

*Assay.* Experiments were performed on 28 rats belonging to five litters, which were similar in age, weight and age at castration to those used in the diol assay. The numbers of rats used in the different groups were: control rats 9, rats injected with 1993, 3986, 7971, 11957 and 15942 $\gamma$ —9, 6, 5, 3, 3 and 2 respectively.

curve (not given here) representing the percentage increase in the weight of the prostate with different doses approximated to a straight line with the smaller doses, *i.e.* between 1993 and 7971 $\gamma$ , after which there was a definite flattening of the curve (Table V). This also occurred with the pure preparation [Korenchevsky and Dennison, 1935, 1, Figs. 1 and 2].

The greatest average percentage increase in the weight of the prostate obtained with the water-soluble preparation (270% actual weight) was also nearly the same as the highest average value given by the fat-soluble preparation [277%; Korenchevsky and Dennison, 1935, 1, Table II, dose 1350 $\gamma$ ].

The reactions of the seminal vesicles were also similar with the two preparations, the percentage increase being in most cases equal to or a little less than that of the prostate (though occasionally with some doses the increase of the seminal vesicles was somewhat larger than that of the prostate). Therefore the average figures of the ratio of the prostate to seminal vesicles were greater than 100 for both preparations (Table VIII). The greatest average percentage increases obtained in the weights of the seminal vesicles with the two preparations were also similar, being 287% with fat-soluble androsterone [Korenchevsky and Dennison, 1935, 1, Table VI] and 300% with w.-s. androsterone.

This same similarity in maximum reaction to the two preparations was also seen with the penis, in which the greatest average percentage increase was 116% with the fat-soluble and 110% with the water-soluble preparation. This organ also showed the same flattening of the curves of percentage increase in weight with the higher doses (see Table VI, this paper, and Table VI, Korenchevsky and Dennison [1935, 1]).

Table VI. *Effect of w.-s. androsterone on prostate weighed with seminal vesicles, penis, preputial glands and thymus.*

Organs	Weights	Average % change in weight of organs of rats injected with $\gamma$				
		1993	3986	7971	11957	15942
Prostate with seminal vesicle	{ Actual	+ 35	+ 103	+ 198	+ 240	+ 269
	{ Per unit body weight	+ 40	+ 100	+ 202	+ 259	+ 263
Penis	{ Actual	+ 17	+ 54	+ 43	+ 95	+ 107
	{ Per unit body weight	+ 23	+ 51	+ 46	+ 110	+ 107
Preputial glands	{ Actual	+ 32	+ 74	+ 69	+ 94	+ 76
	{ Per unit body weight	+ 37	+ 72	+ 68	+ 112	+ 73
Thymus	{ Actual	- 15	- 24	- 14	- 33	- 28
	{ Per unit body weight	- 11	= 0	- 9	- 28	- 28

The reaction of the preputial glands was less with the water-soluble than with the fat-soluble preparation (see the same tables), the largest figures of percentage increase being 112 and 164 respectively. The reaction of the preputial glands however is always so irregular that it is not possible to attach much importance to this difference.

With nearly all the doses used the weight of the thymus decreased slightly (Table VI). There was no change in the fat deposition. The other organs were not investigated in these experiments.

*The rat unit of w.-s. androsterone.* The curve of the percentage increase in the weight of the prostate over the range 0-7971 $\gamma$  approximates to a straight line, *i.e.* for this range a direct proportional relationship between the dose and the effect may be assumed. This is seen particularly clearly in the average figures per 200 g. of body weight (Table V). It therefore seems to be justifiable

to calculate the rat unit from the average of the effects produced by the doses within this range, *i.e.* by 1993, 3986 and 7971 $\gamma$ . In this case one rat unit of "comb-growth activity" is contained in about 1.6 mg. and one rat unit of "whole male sexual activity" in about 1.7 mg. These quantities of the water-soluble androsterone salt contain about 1.19 and 1.21 mg. of pure crystalline androsterone.

Since one rat unit was contained in about 170 $\gamma$  of pure androsterone dissolved in oil [Korenchevsky and Dennison, 1935, 1], we must conclude that androsterone administered as the pure substance dissolved in oil is more active than the water-soluble salt of the ester.

*Statistical description of the curves.* J. M. C. Scott, under direction of Prof. E. S. Pearson (Department of Statistics, University College), has represented graphically in the form of the above curves the results of the assay, and the same statistical method as used in the previous paper [Korenchevsky and Dennison, 1935, 2] was again employed.

### DISCUSSION.

#### *The comparison of the effects of water-soluble diol and fat-soluble diol.*

Since each of the preparations used was injected in different doses, it is not easy to make a comparison of the two preparations. Some of the figures in the tables of the previous and present papers however provide suitable data, and other data are summarised in Table VII, in which only the actual weights are tabulated since they differed little from those per unit of body weight.

Table VII. *Comparison of the effect of w.-s. diol\* with that of fat-soluble diol.*

% increase in weight of organs per 100 $\gamma$ of the injected doses						
Preparations of diol	Doses* injected $\gamma$	Seminal vesicles	Prostate	Prostate + seminal vesicles	Penis	Preputial glands

13. )	2321	57	24	27	7	8
14. Fat-soluble	{ Av. for doses 25-200	223	144	156	100	37
15. Water-soluble*	Av. for all doses	84	54	59	27	19

\* Doses for w.-s. diol are given as the amount of cryst. diol contained in the water-soluble salt.

(1) It can be seen from Tables II to IV of the previous paper that in all the organs a sharp flattening of the curve occurs after the injection of 200 $\gamma$  of fat-soluble diol, whilst after the injection of the water-soluble salt containing 2321 $\gamma$  of pure diol (the highest dose used) sharp flattening had still not been reached.

Thus, with 350 $\gamma$  of "fat-sol. diol" the percentage increases in the actual weights of the seminal vesicles, prostate and penis were 314, 198 and 102 respectively and with 2321 $\gamma$  of diol in the "w.-s. salt" were 1317, 546 and 164 respectively.

With the fat-soluble preparation therefore a very pronounced flattening of the curves occurs with much smaller doses than with the water-soluble preparation. This explains why it is possible to obtain a much greater increase in the weight of the atrophied organs by the injection of the water-soluble preparation than with the fat-soluble preparation.

(2) The stimulation of the growth of the organs with both the fat-soluble (lines 3-7, Table VII) and the water-soluble (lines 8-13, Table VII) preparations becomes less per unit (100 $\gamma$ ) of the preparation as the dose is increased.

The fat-soluble preparation however produces a greater effect per 100 $\gamma$  than the water-soluble preparation (compare lines 3-7 with lines 8-13, Table VII).

This difference is seen particularly clearly if similar doses are chosen. Since the doses 74 and 148 $\gamma$  (lines 8 and 9, Table VII) of w.-s. diol produce nearly the same effect per unit dose, this effect would presumably be produced by all doses between 74 and 148 $\gamma$ , including the dose 100 $\gamma$ , the probable effect of which is interpolated in line 2 of Table VII. The dose 100 $\gamma$  of fat-soluble diol was actually used for injection (line 1, Table VII). Comparison of the effects of 100 $\gamma$  of the two preparations shows that the fat-soluble preparation produces a considerably greater effect than that produced by the water-soluble preparation.

In spite of this, however, the increase in the effect by increasing the large doses and thus producing the largest possible reaction was, as stated in the previous paragraph, more pronounced in the case of the water-soluble preparation. This is of course only true for the concentrations of fat-soluble diol used.

(3) The two previous sections have described the differences between the water-soluble and fat-soluble preparations. The points of similarity between the two substances have already been mentioned in this and the previous papers. With both preparations the "effect per 100 $\gamma$ " decreases as the dose increases and the stimulation of the growth of seminal vesicles is greater than that of the prostate.

#### *The difference between the actions of diol and of androsterone.*

As far as can be judged from experiments of 7 days of injection, the chief difference between androsterone and diol is that androsterone does not stimulate the growth of the prostate and seminal vesicles in a normal relation, as is done by diol. This is true for both the fat-soluble and water-soluble preparations.

The seminal vesicles atrophy after castration to a much greater extent than the prostate, the average weights of the seminal vesicles and prostate 30 days after castration being about 10-12 mg. and 50-55 mg. respectively. Since the weights of these two glands are approximately equal in the normal adult rat, it is clear that, if both these structures are to be restored to the normal condition, injections of the hormone should produce a greater percentage increase in the weight of the seminal vesicles than in that of the prostate.

The ratios of  $\frac{\% \text{ increase of prostate}}{\% \text{ increase of seminal vesicles}} \times 100$  for both water-soluble and fat-soluble preparations of androsterone and diol are given in Table VIII. It can be clearly seen from this table, that whilst for androsterone on the average this ratio is greater than 100, for diol it is about 60, i.e. whilst androsterone stimulates the growth of the seminal vesicles and prostate equally in most of the rats and

Table VIII. *Ratio ( $\times 100$ ) of percentage increase in weight of prostate to that of seminal vesicles after injection of different doses of fat-soluble and water-soluble preparations of androsterone and androsterone-diol.*

in some has even more effect on the prostate than on the seminal vesicles, diol produces a greater effect on the seminal vesicles than on the prostate. Thus diol produces a return towards the normal ratio in the development of these glands, whilst androsterone is unable to do so. In 7-day experiments maximum doses both of w.s. and f.s. preparations of androsterone produced about the same effects in spite of great quantitative difference of these doses; whilst the maximum dose of diol in w.s. form had greater action than that of f.s. preparation.

These dissimilarities in the reaction of the seminal vesicles and in the values of the rat units are the chief differences between the androsterone and diol preparations. As the reaction of the seminal vesicles is not always so regular as that of the prostate, the introduction of one more rat unit (measuring the activity in producing growth of the seminal vesicles) would present difficulties.

On the other hand the unit of "whole male sexual activity" does not demonstrate sufficiently sharply this important difference between the reaction of the seminal vesicles and of the prostate.

Therefore in assays made by our method we suggest the additional use of the ratio—percentage increase in weight of prostate to that of the seminal vesicles—which, considered in conjunction with the size of the rat units, may serve as an important point for differentiating between the two substances.

#### *The difference in the effects on capons and on castrated rats.*

As was stated at the beginning of the paper, Tschopp found that the activity of water-soluble androsterone (c.v.=80–100 $\gamma$ ) on the comb-growth of capons was about twice that of water-soluble diol (c.v.=about 200 $\gamma$ ).

As compared with this ratio the reaction of castrated rats was found to be entirely different, both quantitatively and qualitatively. We found that one rat unit was contained in about 1600 $\gamma$  of w.s. androsterone and in 67 $\gamma$  of w.s. diol, i.e. diol was about 24 times more active than androsterone. Therefore with these two preparations, the reactions of capons (Tschopp's values) and rats show an inverse relationship.

Since the human being is a mammal, the importance of making an assay on mammals (in particular on rats) in addition to the comb-growth assay is thus emphasised. Sooner or later the results obtained with birds must show differences from those on mammals and of this the above is a good example.

#### SUMMARY.

1. The water-soluble lithium salt of the monosuccinic ester of androsterone and the water-soluble lithium salt of the monosuccinic ester of androsterone-diol were assayed on 99 rats belonging to 18 litters, and the effects of these substances compared with those of pure androsterone and pure diol dissolved in oil.

2. The chief effects of the water-soluble and fat-soluble preparations of androsterone were similar, as was also the case with the two preparations of diol.

3. The chief point of similarity in the androsterone preparations was that the average effect on the prostate was about the same or a little greater than that on the seminal vesicles. The average ratio ( $\times 100$ ) of the increase in the prostate to that of the seminal vesicles (actual weights) was 106 for the fat-soluble and 129 for the water-soluble preparation.

4. The main points of similarity between the diol preparations are (i) the greater quantitative effect as compared with the androsterone preparations and (ii) the fact that they stimulate the growth of the seminal vesicles more than that of the prostate, the average ratio ( $\times 100$ ) of the percentage increase in the prostate to that of the seminal vesicles (actual weights) being 64 for fat-soluble and 63 for water-soluble diol.

5. Therefore, in addition to the difference in the value of the rat units, the difference in this ratio must be considered as one of the important points distinguishing diol from androsterone in assay experiments on rats.

6. The rat unit of "comb-growth activity" was contained in about 1600 $\gamma$  of water-soluble androsterone and in about 67 $\gamma$  of water-soluble diol.

7. Whilst the ratio of the rat unit of pure androsterone to the rat unit of the water-soluble salt of the ester was about 1/9, the ratio for the corresponding diol preparations was about 1/3.

8. Whilst on capons it was found that water-soluble androsterone was about twice as active as water-soluble diol, in the present experiments on rats diol proved to be about 24 times more active than androsterone.

9. Other points of similarity and difference between the preparations of androsterone and androsterone-diol were discussed.

Grants from the Lister Institute and from the Medical Research Council have enabled us to carry out this work and to them our thanks are due. We are much indebted to Prof. E. S. Pearson, Mr J. M. C. Scott and the Department of Statistics of University College for the statistical investigation of the results obtained.

## CCLV. STUDIES IN FAT METABOLISM.

### I. THE OXIDATION OF BUTYRIC, CROTONIC AND $\beta$ -HYDROXYBUTYRIC ACIDS IN PRESENCE OF GUINEA-PIG LIVER SLICES.

By MAURICE JOWETT<sup>1</sup> AND JUDA HIRSCH QUASTEL.

*From the Biochemical Laboratory, Cardiff City Mental Hospital.*

*(Received July 11th, 1935.)*

UNTIL lately the study of the metabolism of fatty acids has depended on methods with which it is difficult to obtain quantitative results and comparisons.

Recently, however, Quastel and Wheatley [1933] have found that fatty acids are oxidised at considerable rates by slices of liver *in vitro* and give as one of their oxidation products acetoacetic acid, as in the body. Modern micromanometric technique can, therefore, now be applied to problems of fatty acid metabolism.

In the present work a study has been made of the kinetics of the oxidation of butyric, crotonic and  $\beta$ -hydroxybutyric acids by the liver of the guinea-pig, and this has led to a partial elucidation of the mechanisms by which these substances are oxidised to acetoacetic acid.

#### EXPERIMENTAL METHODS.

The manometric methods of Warburg [1926] have been used throughout. Measurements of respiration have been made by immersing tissue slices in a medium containing sodium  $\beta$ -glycerophosphate as buffer, 0.2 ml. of 6% KOH being present in a side-tube of the manometric vessel. Estimations of acetoacetic acid have been made in the solutions after removal of the tissue slices. The experimental period has usually been two hours at 37°. The mean rates for respiration refer to the period  $\frac{1}{2}$  to 2 hours and those for acetoacetic acid formation to the period 0 to 2 hours.

In accordance with the notation introduced by Warburg, the respiration ( $Q_{O_2}$ ) is defined as the number of  $\mu$ l. of oxygen (reduced to N.T.P.) absorbed per mg. dry weight of tissue per hour, and the rate of production of acetoacetic acid ( $Q_{Ac}$ ) is similarly defined in terms of gas evolution. Our manometric method of estimating acetoacetic acid gives an evolution of one molecule of carbon dioxide per molecule of acetoacetic acid. Hence  $Q_{Ac}$  can be regarded as measured in terms of volumes of  $CO_2$ , or, according to the usual convention, as measured in terms of the volume which acetoacetic acid would occupy if it behaved as a perfect gas at N.T.P.

*Media.* All solutions have been so made up as to have an osmotic pressure approximately equal to that of 0.16 *M* NaCl. Uni-univalent salts employed are made up in stock solutions to 0.16 *M*, or to submultiples of this strength, dilutions being made with 0.16 *M* NaCl. Salts of other valency-types are made up to the appropriate strengths, *e.g.* sodium fumarate to 0.107 *M*. With solutions so

<sup>1</sup> Beit Memorial Research Fellow.

made up, the medium in which the tissue is immersed can readily be made isotonic by mixing the various stock solutions.

The volume of medium used in each vessel has been usually 3.2 ml., this choice of volume being convenient for performing dilutions. The volume is made up to 3.2 ml. with 0.16 *M* NaCl after all other desired substances are present.

The composition of a typical medium is as follows:

Sodium glycerophosphate	...	...	0.067 <i>M</i>
KCl	...	...	0.002 <i>M</i>
CaCl <sub>2</sub>	...	...	0.001 <i>M</i>
Sodium butyrate	...	...	0.01 <i>M</i>
NaCl	...	...	0.051 <i>M</i>

In all media employed, unless otherwise stated, the concentration of K<sup>+</sup> is 0.002 *M*, and that of Ca<sup>++</sup> 0.001 *M*.

*Glycerophosphate buffer.* Quastel and Wheatley [1933] found that phosphate inhibited partially the oxidation of butyric acid to acetoacetic acid by liver. Phosphate buffer solutions precipitate calcium ion and cannot be used in a medium of the Locke type. Following Quastel and Wheatley, we have therefore adopted sodium  $\beta$ -glycerophosphate as a buffer. The salt is brought to *p*<sub>H</sub> 7.4 with HCl, and a 0.105 *M* solution is used, of which usually 1.9 ml. are present in a total volume of 3.2 ml.

According to Meyerhof and Kiessling [1933] *p*<sub>K'</sub> for  $\beta$ -glycerophosphoric acid is about 6.33; hence at *p*<sub>H</sub> 7.4 the buffering action is weak, particularly in the direction of rising *p*<sub>H</sub>. Quastel and Wheatley [1934] reported a drop in *p*<sub>II</sub> of about 0.2 during experiments of 3 hours' duration with guinea-pig and rat liver slices. Glycerophosphate solutions undergo hydrolysis on keeping, with liberation of phosphate and fall of *p*<sub>II</sub>. They may however be kept several days at 0° without much change.

*Tissue slices.* It has been found that the accuracy of the experiments depends mainly on the use of slices of similar thickness throughout any one experiment. The thickness of slices used varies from one experiment to another, but has usually lain between the limits 0.25–0.45 mm. Several slices are commonly employed in each vessel, since the total dry weight desired has usually been 15–25 mg. The use of several slices appears to help to smooth out differences of behaviour.

*Livers.* The livers of young guinea-pigs, mainly of weights 270–330 g., fed on bran, oats and greens, have been employed. The animals were bled from the throat before removing the livers, the blood of which is therefore partially removed.

*Neutralisation of acids.* All fatty and other acids are neutralised before use, solutions of the sodium salts being prepared.

*Manometric estimation of acetoacetic acid.* As was found by Quastel and Wheatley [1933], acetoacetic acid can be estimated manometrically by measurement of the volume of gas produced in its breakdown to acetone and carbon dioxide, aniline being used as a catalyst for the process.

Acetoacetic acid breaks down spontaneously in solution, giving the same end-products except in very alkaline solutions [Widmark, 1920]. The rate of breakdown is slow in neutral solutions but becomes faster in acid solutions. Below are given some data on this point calculated from the measurements of Widmark.

Values of the rate of decomposition have also been measured by us manometrically, and are summarised in the last column of the table. The agreement with the figures of Widmark is quite satisfactory.

*Decomposition of acetoacetic acid at 37°.*

$k_{uni}$ (min.) (W.)	$p_H$	% decomposition		$k_{uni}$ (J. and Q.)
		In 15 min.	In 2 hours	
4.5 .10 <sup>-3</sup>	<2.0	6.5	41.7	4.8 .10 <sup>-3</sup>
1.31 .10 <sup>-3</sup>	4.0	1.9	14.6	—
5.8 .10 <sup>-4</sup>	4.5	0.9	6.7	5.5 .10 <sup>-4</sup>
2.5 .10 <sup>-4</sup>	5.0	0.4	3.0	—
8.0 .10 <sup>-5</sup>	7-8	0.1	1.0	(2 .10 <sup>-4</sup> )

The table shows that acetoacetate formed in neutral solutions, as in our experiments with tissues, will not be appreciably decomposed during experiments of two hours' duration, by the homogeneous process here considered.

For the estimation of acetoacetic acid, the neutral buffered solutions used in tissue experiments must be acidified to a  $p_H$  of 5 or below before adding the aniline catalyst in order to avoid retention of carbon dioxide by the medium. The table shows that the solution can be kept at 37° for 15 min. at  $p_H$  4.5 with less than 1 % loss of acetoacetic acid.

We have therefore usually employed the following technique. At the end of the experiment, the tissue slices are removed from the manometer vessels. The residual solution, usually 3.2 ml., is at once acidified by adding 0.3 ml. of a suitable solution of acetic acid or acetic-acetate buffer, which brings it to a  $p_H$  near 4.5 (B.D.H. "4.5" indicator may be used). 0.2 ml. of a solution of aniline hydrochloride containing 0.09 g. of the salt is run into a side-tube of the vessel<sup>1</sup>. The vessel, attached to its manometer with air as gas phase, is then shaken for 15 min. in the thermostat at 37° before the manometer is read and the aniline salt is added to the solution containing acetoacetic acid. The acetoacetic acid is now decomposed according to a unimolecular law, the precise rate depending on the buffering of the solution, which determines the  $p_H$  it assumes on addition of the more acid aniline hydrochloride solution. According to Widmark and Jeppsson [1922] the optimum  $p_H$  for the reaction is about 4.1, but we have not troubled to choose conditions which are exactly optimum. Under our conditions the acetoacetic acid is half decomposed in 5-6 min. and after 50 min. evolution of gas may be considered complete.

Addition of the concentrated aniline hydrochloride to solutions containing no acetoacetic acid results in evolution of gas (some 8 mm. of Brodie's fluid or 12  $\mu$ l. of gas under the conditions described), presumably due to expulsion of air and a "blank" correction, which need not be determined in every experiment, must be applied.

In tissue experiments where no acetoacetic acid was expected to be formed, the pressure changes obtained when corrected for "the blank" have sometimes given slightly negative values. This absorption is probably due to a very small oxygen uptake by tissue debris or extract, which continues after addition of aniline. Its magnitude has always been less than about 8  $\mu$ l. and it has been neglected.

The CO<sub>2</sub> outputs from sodium acetoacetate solutions made by hydrolysing known amounts of ethyl acetoacetate have been measured and values up to 97-98 % of the theoretical have been obtained. Since the acetoacetate solutions are unstable even when kept at 0°, we take this to indicate a real and exact equivalence between CO<sub>2</sub> output and acetoacetic acid.

<sup>1</sup> If a side-tube of the vessel previously contained alkali (to absorb CO<sub>2</sub>), the alkali is removed with filter-paper, and the side-tube rinsed with dilute acid and roughly dried, employing filter-paper again.

The method is suitable for measuring quantities of acetoacetic acid which give 100  $\mu$ l. of  $\text{CO}_2$  and upwards. For 10–20  $\mu$ l. the accuracy is doubtful, but the errors will probably be of a similar order in estimations made in any one experiment.

A question to be considered is whether for the purposes of this work the manometric method is specific for acetoacetic acid, or whether other substances, and in particular other  $\beta$ -keto-acids, will react similarly with aniline.

Oxaloacetic acid reacts with aniline, but much more rapidly [Ostern, 1933], so that if quantities appreciable in relation to acetoacetic acid were present they could be detected by a rapid fall in the unimolecular constant of the reaction. No such indications of the formation of oxaloacetic acid have been found in this work.

This work, together with that of Quastel and Wheatley [1933; 1934], is apparently the first in which the formation of acetoacetic acid from fatty acids by the liver has been measured as such. Embden and Marx [1908] distilled their solutions after each experiment and obtained in the distillate an iodoform-yielding substance, presumed to be acetone and in some cases identified as acetone. Embden and Engel [1908] showed in some cases that the iodoform-yielding substance was preformed in the solutions only to a small extent and was mainly formed on heating. There was thus a strong presumption that acetoacetic acid is the product chiefly in question, but conceivably, as Hurtle pointed out [1916], it might be acetonedicarboxylic acid.

#### RESPIRATION AND ACETOACETIC ACID PRODUCTION.

In Fig. 1 are given curves showing the manner in which the rate of acetoacetic acid production ( $Q_{Ac}$ ) by liver slices varies with the concentration of the substrate in the medium. In the absence of added substrate,  $Q_{Ac}$  has a small but

Fig. 1. Rates of acetoacetic acid production by guinea-pig liver. [Oxygen; glycerophosphate buffer.]

definite value. At low concentrations of fatty acid,  $Q_{Ac}$  increases approximately proportionally to the concentration. With butyric acid,  $Q_{Ac}$  reaches almost its highest value at a concentration of 0.01  $M$ , with  $\beta$ -hydroxybutyric acid the saturation concentration is more nearly 0.03 or 0.04  $M$ . With crotonic acid, however,  $Q_{Ac}$  passes through a maximum at a concentration of about 0.015–0.02  $M$ . The curves are smoothed curves drawn by combining the results of several experiments.

The behaviour of butyric and  $\beta$ -hydroxybutyric acids is normal, whilst it appears that crotonic acid in some manner inhibits its own oxidation at high concentrations.

*Influence of ionic environment on acetoacetic acid production.*

The rate of production of acetoacetic acid is also influenced by the concentration of potassium and calcium ions in the medium, at least in the case of butyric and crotonic acids. Experiments are given in Table I showing the effect of varying (a) the potassium ion concentration, (b) the calcium ion concentration and (c) both potassium and calcium ion concentrations.

Table I. *Effect of varying potassium and calcium ion concentrations.*

Guinea-pig liver. Oxygen. Glycerophosphate buffer.

Exp.	Substrate (M)	Concentrations (M)			
		[K <sup>+</sup> ]	[Ca <sup>++</sup> ]	Q <sub>O<sub>2</sub></sub>	Q <sub>V</sub>

		0.001	0.001	8.37	2.98
		0.002	0.001	9.13	3.10
		0.005	0.001	9.20	2.99
2	Butyrate 0.01	0.002	0	8.56	1.98
		0.002	0.001	8.70	2.93
		0.002	0.002	8.01	2.50
		0.002	0.004	7.86	2.54
3	Butyrate 0.01	0	0	7.24	1.64
		0.001	0.0005	9.50	3.32
		0.002	0.001	9.13	3.20
		0.005	0.0025	8.85	2.71
4	Crotonate 0.02	0.002	0	7.37	1.69
		0.002	0.0005	7.89	2.28
		0.002	0.001	7.92	2.35
		0.002	0.002	7.44	2.22
5	Crotonate 0.01	0	0	5.88	1.83
		0.0005	0.00025	7.57	2.34
		0.002	0.001	7.77	2.58
6	$\beta$ -Hydroxybutyrate 0.01	0	0	4.25	1.46
		0.0006	0.0003	5.03	1.20
		0.002	0.001	4.89	1.39

The experiments show that with crotonic and butyric acids  $Q_{V_0}$  has optimum values when [K<sup>+</sup>] is about 0.002 *M* and [Ca<sup>++</sup>] is about 0.001 *M*. These concentrations of potassium and calcium ions have therefore been maintained in the media throughout the rest of this work.

On the other hand, the production of acetoacetic acid from  $\beta$ -hydroxybutyric acid is not definitely influenced by the ionic environment.

It has been found that the rate of acetoacetic acid production from butyrate is approximately the same in a glycerophosphate medium as in Ringer's solution, when the initial  $p_H$  of both media is 7.4. It is therefore unlikely that  $\beta$ -glycerophosphate has any great specific action on the oxidation of fatty acids.

*Effect of  $p_H$  variation on acetoacetic acid formation.*

The effect of varying the  $p_H$  of the medium is shown in Table II, where in the several vessels employed in each experiment the same mixture of O<sub>2</sub> and CO<sub>2</sub> is present, and the bicarbonate concentration is varied. Bicarbonate-CO<sub>2</sub> here replaces glycerophosphate as buffer. The experiments show that, with all three

Table II. *Effect of  $p_H$  on rate of production of acetoacetic acid by guinea-pig liver.*

$O_2 + CO_2$ .  $p_H$  varied by variation of bicarbonate concentration and calculated roughly to midpoint of experiment by assuming  $Q_{CO_2} = 3.5$ .

Exp.	Substrate	Initial	Relative values for $Q_{Ac}$ at $p_H$				
		$\frac{O}{CO_2}$	6.8	7.1	7.4	7.7	8.0
1	Butyrate 0.01 <i>M</i>	5	60	84	100	97	—
2	Butyrate 0.01 <i>M</i>	1.3	—	89	100	87	70
3	$\beta$ -Hydroxybutyrate 0.01 <i>M</i>	5	54	72	100	78	—
4	$\beta$ -Hydroxybutyrate 0.02 <i>M</i>	1.5	—	89	94	100	95
5	Crotonate 0.02 <i>M</i>	5	57	83	81	100	—
6	Crotonate 0.02 <i>M</i>	5	58	70	91	100	—
7	Crotonate 0.02 <i>M</i>	1.3	—	65	89	100	95
8	Crotonate 0.02 <i>M</i>	1.3	—	72	85	100	98

Hence approximate optimum  $p_H$  values are: butyrate 7.4–7.6;  $\beta$ -hydroxybutyrate 7.4–7.7; crotonate 7.7–7.9.

acids, the rate of formation of acetoacetic acid varies considerably with the  $p_H$ , the variation being of the same order as is shown in glycolysis [Warburg *et al.*, 1924].

In the case of butyrate and  $\beta$ -hydroxybutyrate,  $Q_{Ac}$  is maximum at about the physiological  $p_H$ , whilst in the case of crotonate the optimum is displaced definitely to the alkaline side.

#### *Mean rates of acetoacetic acid formation.*

In Table III are assembled data showing the mean rates of acetoacetic acid formation from the three acids. It is evident that the highest rate is given by butyric acid, followed closely by crotonic acid, whilst the rate from  $\beta$ -hydroxybutyric acid is appreciably lower. The rate of acetoacetic acid formation by the

2.8–3.6	13	3.67–5.93	4.84	$\pm 0.62$
3.7–4.4	20	4.21–5.52	4.96	$\pm 0.35$
4.5–7.2	20	3.85–6.84	5.39	$\pm 0.75$

liver in absence of added fatty acid is low, too low for accurate measurement, and can for most purposes be neglected in considering the acetoacetic acid formation in presence of added fatty acid.

$Q_{Ac}$  varies considerably from one liver to another. Experiments seem to indicate that the state of nutrition plays a part, for  $Q_{Ac}$  in the case of butyrate as substrate appears to be higher when the animal has been starved for 24 hours before being killed. This type of effect, which requires further investigation, may throw light on the question whether fatty acid substrates compete with carbohydrates for oxidation, or whether, as is sometimes suggested, "fats burn in the fire of the carbohydrates".

The size of the liver in young guinea-pigs is very variable. In considering this matter, we use the weight of the liver (wet weight) expressed as a percentage of the weight of the animal. The figures for 120 animals show a variation of this percentage between 2.6 and 7.2; 50% of the figures lie between 3.6 and 4.5, 75% between 3.3 and 5.1, and 90% between 3.1 and 5.6. The data given in Table III show that the weight of the liver is a factor in determining  $Q_{Ac}$ . In the case of butyrate as substrate heavy livers give lower values of  $Q_{Ac}$ . The same is true for crotonate, for which the data are not given.

Data on the respiration of liver in absence of added substrates have been calculated (Table III), which show that  $Q_{O_2}$  does not vary very significantly with the weight of the liver. The tendency is for larger livers to give higher values for  $Q_{O_2}$ , but the most definite finding is that the respiration of medium-sized livers is less variable than that of light or heavy livers. Further investigation is desirable to show whether or not the percentage of fat in the liver, which may influence considerably the dry weight (used in calculating metabolic quotients), varies with the size of the liver.

*Correlation between acetoacetic acid production and increased respiration.*

It is shown in Table IV that, when butyrate or crotonate is present in the medium, the respiration of the tissue is raised. There is found to be a very close correlation between the increase in the rate of production of acetoacetic acid, i.e.  $Q_{Ac}$ , and the increase in respiration,  $Q_{O_2}$ . The ratio between the two increases

Table IV. *Acetoacetic acid formation and oxygen consumption.*

15	5.79	0.68	"	6.84	1.90	1.25
16	4.93	0.24	$\beta$ -Hydroxybutyrate 0.02 <i>M</i>	6.88	1.94	0.87
17	5.79	0.68	"	7.45	2.44	1.06

is constant almost within the experimental error. Under the given conditions the ratio has the mean value 0.63 for butyrate and 0.73 for crotonate. Possibly also in the case of  $\beta$ -hydroxybutyrate the variation does not exceed experimental error.

The value of the ratio, however, depends on the concentration of the substrate (Table V). It is noteworthy that on continuing to increase the substrate concentration beyond the point at which  $Q_{Ac}$  has reached its highest value, the respiration continues to rise. There is an indication here that the oxidation of the substrates follows two different paths, one to acetoacetic acid and another to some other product or products.

*Relative rates of acetoacetic acid production from butyric and crotonic acids.*

A series of experiments has been made in which the actions of each liver on butyric and crotonic acids have been compared (Table VI). It will be seen that a close parallelism exists between the values of  $Q_{Ac}$  observed for the two acids. A liver that gives a low value with one acid gives a low value for the other. Crotonic

acid gives lower values for  $Q_{Ac}$  than does butyric acid, and at a given concentration the ratio of the values of  $Q_{Ac}$  is almost constant, having a maximum value (0.9) at the concentration of crotonate which gives maximum values of  $Q_{Ac}$  (0.015–0.02  $M$ , Fig. 1). This close parallelism between the values of  $Q_{Ac}$  is a strong indication of some similarity in the mechanism of oxidation of the two acids.

*Competition between substrates.*

Results are given in Table VII of some experiments on the respiration and acetoacetic production when two of the acids are present together.

When  $\beta$ -hydroxybutyrate and butyrate are present together, the rates of production of acetoacetic acid from the two substances are not additive. Yet

although  $Q_{Ac}$  from butyrate is approximately maximum, the value of  $Q_{Ac}$  can be raised by the presence of  $\beta$ -hydroxybutyrate. It is evident, therefore, that the production of acetoacetic acid from these two substances may proceed, at least partially, by quite independent paths.

On the other hand, when crotonate is added to butyrate,  $Q_{Ac}$  is lowered. The experiments agree with the view that, when both acids are present, crotonate exerts on the oxidation of butyrate the same inhibitory action that it exerts on its own oxidation at sufficiently high concentrations. There is no evidence that the acids are oxidised to acetoacetic acid by independent paths.

It may be mentioned here that under anaerobic conditions guinea-pig liver does not oxidise butyric, crotonic or  $\beta$ -hydroxybutyric acid appreciably to acetoacetic acid. This was shown by experiments similar to those already recorded, except that nitrogen replaced oxygen in the gas phase. The highest value of  $Q_{Ac}$  found was 0.14, which does not exceed the experimental error.

*The action of inhibitors.*

The action of a number of substances likely to inhibit the oxidation of one or more of the fatty acids was investigated largely with a view to finding differential effects on one or more of the acids, which might give information regarding the mechanisms of the oxidations.

It will be seen (Table VIII) that among the substances examined are several unsaturated compounds, which, it was thought, might inhibit particularly the oxidation of crotonic acid. This however was not found to be the case, although there is one possible exception.

With all substances examined which cause much inhibition of acetoacetic acid formation, the effects on crotonic acid and butyric acid are very similar, with the qualification that as a rule the inhibition is slightly greater for crotonic acid (Table VIII).

The inhibitory action of propionate on oxidation of butyrate had already been found by Quastel and Wheatley [1933]. It is now found that oxidation of crotonate is inhibited to a similar extent, whilst that of  $\beta$ -hydroxybutyrate is only very slightly lowered. Propionate is itself oxidised by the liver without acetoacetic acid formation.

Acrylate<sup>1</sup> exerts an inhibitory action on acetoacetic acid formation similar to, but weaker than, that of propionate and like propionate increases the respiration of guinea-pig liver, but to a smaller extent.

Allyl alcohol, already known as a powerful respiratory poison, inhibits the respiration of liver strongly, its action being progressive with time. It lowers  $Q_{A_0}$  in presence of crotonate and butyrate still more strongly, inhibition being still in evidence at a concentration of 0.0003 *M*. Observations suggest that at low concentrations the alcohol is strongly taken up by the tissue, since the inhibition seems to depend on the weight of tissue present. Allyl alcohol is not therefore convenient for quantitative experiments.

Several powerful inhibitors have been found in the aromatic series. Cinnamic,  $\beta$ -phenylpropionic and benzoic acids all cause considerable inhibitions of acetoacetic acid formation from butyric and crotonic acids at concentrations of 0.0005 *M*, the inhibition of oxidation of crotonic acid being greater than of butyric acid. The oxidation of  $\beta$ -hydroxybutyric acid is much less inhibited. The aromatic acids mentioned above do not diminish the respiration of the liver in presence of the fatty acids to a greater extent than would be expected from the diminution in production of acetoacetic acid, i.e. on the basis of the relation between respiration and acetoacetic acid production which has already been found (Table IV). The diminution in respiration is in fact usually less than would be expected from the ratios previously given. As far as our experiments go, they indicate that weak solutions of the aromatic acids in question affect no other respiratory processes in the liver than the oxidation of fatty acids to acetoacetic acid.

Our experiments give no indication that these aromatic acids are themselves undergoing appreciable destruction in the liver, as according to the work of Knoop and Dakin they do in the intact organism. If the acids disappeared during our experiments, it might be expected that their inhibitory effect on respiration (due to their inhibitory effect on fatty acid oxidation) would be lessened, and an increase would take place in the respiration relative to the "control". No such phenomenon was observed. It was also observed in one experiment (Table VIII) that the inhibitory effect of benzoate on acetoacetic acid production is independent of the weight of tissue present, which indicates that benzoate is neither very greatly adsorbed nor destroyed by quantities of tissue such as we employ in our work.

Tropic ( $\alpha$ -phenyl- $\beta$ -hydroxypropionic) acid is much less toxic to acetoacetic acid production than are cinnamic and  $\beta$ -phenylpropionic acids.

Fluoride is found to be a strong inhibitor of acetoacetic acid formation from

crotonic and butyric acids. The effect persists down to concentrations of 0.001 *M*. The stronger solutions of fluoride have also a considerable and progressive inhibitory action on respiration, but weaker solutions (say 0.0025 *M*) inhibit respiration no more than would be expected from their effect in diminishing oxidation of the fatty acids. The action of fluoride in weak solutions is probably therefore fairly specific. The inhibitory action on acetoacetic acid formation is exerted at concentrations similar to those at which fluoride inhibits glycolysis [Dickens and Šimer, 1929].

A slight differential effect on the production of acetoacetic acid from butyric acid and crotonic acid is shown by strong solutions of fumarate. Fumarate slightly increases  $Q_{ac}$  in presence of butyrate and decreases it slightly in presence of crotonate. This is the only case we have observed where a substance affects the rates in opposite directions, but the effect does not lie much outside experimental error. Fumarate is itself oxidised by guinea-pig liver.

#### THE MECHANISMS OF THE OXIDATIONS.

It has frequently been suggested that the mechanisms of oxidation of butyric, crotonic and  $\beta$ -hydroxybutyric acids to acetoacetic acid in the liver are related. Friedmann [1908] suggested that  $\beta$ -hydroxybutyric acid occupied an intermediary place between crotonic and acetoacetic acids, and Hurlley [1916] proposed the scheme:

The most elaborate scheme, which Dakin appears to have favoured [1922], allows three different paths for butyric acid:

The arguments used in favour of these various mechanisms are mainly chemical analogies of more or less value, and none of them is decisive.

Our experiments with inhibitors (propionate and cinnamate, Table VIII) show that the oxidation of  $\beta$ -hydroxybutyric acid is hardly affected by conditions which inhibit considerably the oxidation of butyric and crotonic acids to acetoacetic acid. We can conclude with certainty that neither butyric nor crotonic acid is an intermediary in the oxidation of  $\beta$ -hydroxybutyric acid to acetoacetic acid by guinea-pig liver.

The discovery by Quastel and Wheatley [1934] that ascorbic acid has little effect on acetoacetic acid production by rat liver from  $\beta$ -hydroxybutyric acid, whilst it accelerates acetoacetic acid production from butyric and crotonic acids, provides some evidence that the same statement is true for rat liver.

Let us next consider the view, advocated by several authors, that  $\beta$ -hydroxybutyric acid is an intermediary in the oxidation of butyric and crotonic acids to acetoacetic acid. The only clear evidence we have found in the literature bearing

on this view tells against it, this being the evidence due to Marriott [1914], who stated that when butyrate was injected into a fasting dog a rise in the acetoacetic acid content of the blood preceded a rise in the  $\beta$ -hydroxybutyric acid content.

Our own experiments are also very definitely against the view that  $\beta$ -hydroxybutyric acid is an intermediary. In the first place, we have found some additivity between the acetoacetic acid production from butyric acid and  $\beta$ -hydroxybutyric acid (Table VII). In the second place, we find that the rate of acetoacetic acid production from  $\beta$ -hydroxybutyric acid is definitely lower than from crotonic or butyric acid (Fig. 1 and Table III). An examination of the curves and figures provides quite decisive evidence that  $\beta$ -hydroxybutyric acid cannot be an obligate intermediary between crotonic or butyric acid on the one hand and acetoacetic acid on the other. It remains possible that a part of the crotonic or butyric acid passes through  $\beta$ -hydroxybutyric acid as an intermediary, but there is little need to complicate our views with this possibility, for which there is no positive evidence.

Another view which has been advanced is that crotonic and  $\beta$ -hydroxybutyric acids are interconvertible directly by addition or loss of water. We are aware of no evidence which is inconsistent with the alternative view that in the liver crotonic acid is first oxidised to acetoacetic acid and then reduced to  $\beta$ -hydroxybutyric acid. We prefer the second view, which accounts for the fact that the conversion of crotonic acid into  $\beta$ -hydroxybutyric acid by minced dog liver [Friedmann and Maase, 1913] requires the presence of oxygen. Our conclusions up to the present may be summarised by the scheme:

We have not yet considered the evidence that acetoacetic acid is convertible into  $\beta$ -hydroxybutyric acid by the liver but may state that adequate evidence is available.

We turn next to a more difficult problem, the relation between the mechanisms of oxidation of butyric and crotonic acids to acetoacetic acid. Our experiments have shown numerous similarities between the rates of the processes and make it fairly certain that a relation exists. For instance, a close numerical relation is found between the rates in different livers (Table VI), which would hardly be likely to exist if the processes were entirely distinct. The reactions are also competitive—when both acids are present the rate is never higher than when one is present alone (Table VII), which is an indication that the modes of oxidation have some feature in common. We will consider the problem first on the usual lines of classical kinetics, according to which if a relation exists, it must, we consider, take one of the three forms:

1. Butyrate  $\rightarrow$  crotonate  $\rightarrow$  acetoacetate.
2. Crotonate  $\rightarrow$  butyrate  $\rightarrow$  acetoacetate.
3.  $\begin{array}{l} \text{Crotonate} \\ \text{Butyrate} \end{array} \begin{array}{l} \nearrow \\ \nearrow \end{array} \text{X} \rightarrow \text{acetoacetate}$

The weight of the evidence is against the first possibility. Under all circumstances the rate of formation of acetoacetic acid from butyric acid is greater than that from crotonic acid when both are present at their optimum concentrations. This is shown by numerous figures already given, *e.g.* in Table VI. The effects of inhibitors (Table VIII) on the oxidation of crotonic acid tend to be greater than

on that of butyric acid, which cannot be explained on the first scheme. Nor would it be anticipated that a higher concentration of crotonic acid than of butyric acid would be required to attain the optimum rate.

The second scheme, namely

is much more plausible, for the rate of oxidation of butyrate to acetoacetate is always faster than that of crotonate.

One set of facts causes apparent difficulty. Reference to Table II shows that at  $p_H$  7.7–8.0 the rate of oxidation of crotonic acid rises above the level at  $p_H$  7.4, whilst the rate for butyric acid falls below the level at  $p_H$  7.4. Setting the values for  $p_H$  7.4 at 100 for butyric acid and 90 for crotonic acid, values true for a glycerophosphate medium (Table III), it appears that at  $p_H$  7.7–8.0 the rate of oxidation of crotonic acid should be greater than that of butyric acid. But direct comparison of the rates of oxidation of the two acids to acetoacetic acid, at  $p_H$  7.9 in Ringer's solution, shows that even under these conditions butyric acid is oxidised the more rapidly.

Crotonate, however, exerts a secondary inhibitory action on its own oxidation and also on that of butyrate (Table VII), the rate of oxidation of which is lowered to that of crotonate. Taking into account this inhibitory effect, we consider it probable that crotonate is oxidised as fast as butyrate, when both are present at optimum concentrations. We must suppose, therefore, that crotonate is reduced quickly enough to saturate the butyrate-oxidising enzyme, a supposition for which there is no evidence.

It might have been expected that the reduction of crotonate to butyrate would be inhibited by substances that do not affect the oxidation of butyrate. We have, however, found no very striking evidence in favour of greater inhibition of crotonate oxidation than of butyrate oxidation, although certain evidence in this direction exists.

We conclude that this mechanism may be correct, but the evidence is insufficient to establish it.

We turn to the third scheme, which represents the possibility that crotonate and butyrate are oxidised to acetoacetate through a common intermediary. It has already been shown that this cannot be  $\beta$ -hydroxybutyrate, and no other substance suggests itself as a likely intermediary.

In these three mechanisms which have just been considered, the intermediary substances have been considered to be formed as ordinary chemical individuals. A fourth mechanism can be proposed, according to which both crotonate and butyrate are adsorbed by the same enzyme, and both are transformed to acetoacetate while remaining adsorbed on the enzyme surface. In such a process the intermediary stages will not exist as separate molecules, but only in combination with the enzyme. It may be suggested that the reactions which take place are as follows:

A similar method of representing the activation of butyric acid has already been put forward by Quastel [1926]. According to this view, butyrate is desaturated to a product identical with an activated crotonate molecule. The theory is

able to explain the same facts as the second scheme, and also accounts for our failure to find substances which inhibit the oxidation of crotonate to any definite extent without also inhibiting oxidation of butyrate. On the basis of the theory, the facts indicate that crotonate has a lower affinity for the enzyme than has butyrate. We should account most readily for the approximate equality of rates of oxidation of the two acids by assuming that the second stage in the process, which is identical for the two acids, is a slower reaction than the first stage. The evidence is insufficient to decide between the second and fourth schemes proposed. We, however, favour the latter, which in its suggestion of a process taking place entirely on the surface of one enzyme is in line with certain facts related to the oxidation of higher fatty acids, which are discussed in the following paper.

## SUMMARY.

1. The rates of oxidation of butyric, crotonic and *dl*- $\beta$ -hydroxybutyric acids to acetoacetic acid by slices of guinea-pig liver in the presence of oxygen have been investigated.
2. The rate of acetoacetic acid production ( $Q_{Ac}$ ) varies in the normal manner as a function of substrate concentration with butyric and  $\beta$ -hydroxybutyric acids, but passes through a maximum value when crotonic acid is the substrate.
3. The rate of acetoacetic acid production from butyric and crotonic acids varies with the potassium and calcium ion concentrations in the medium and passes through a maximum value.
4. The optimum  $p_H$  for the oxidation is close to the physiological value for butyric and  $\beta$ -hydroxybutyric acids but lies a little to the alkaline side (7.7–7.9) for crotonic acid.
5.  $Q_{Ac}$  in presence of butyrate is slightly greater than in presence of crotonate under optimum conditions. The ratio of the rates is fairly constant when measured under definite conditions.  $Q_{Ac}$  in presence of  $\beta$ -hydroxybutyrate is considerably lower.
6. There is a definite correlation between the increase in respiration and the increase in  $Q_{Ac}$  brought about by the acids.
7. Experiments with mixtures of the acids show that there is competition between butyric and crotonic acids for oxidation, but partial additivity with  $\beta$ -hydroxybutyric acid.
8. Benzoate, cinnamate and phenylpropionate inhibit strongly the oxidation of butyric and crotonic acids to acetoacetic acid. At low concentrations (0.001 *M*) they appear to inhibit specifically the oxidation of fatty acids.
9. Cinnamate and propionate inhibit the oxidation of  $\beta$ -hydroxybutyric acid to a much smaller extent than the oxidations of butyric and crotonic acids.
10. The evidence supports the scheme of reaction:

11. It is possible that crotonate passes through butyrate as an intermediary. It is rather more probable that the process of oxidation to acetoacetate takes place at one and the same enzyme, which effects the complete process with both butyrate and crotonate.

One of the authors (M. J.) wishes to express his thanks to the Medical Research Council for a personal grant. The authors also wish to thank this body for a grant in aid of equipment.

# CCLVI. STUDIES IN FAT METABOLISM.

## II. THE OXIDATION OF NORMAL SATURATED FATTY ACIDS IN THE PRESENCE OF LIVER SLICES.

BY MAURICE JOWETT<sup>1</sup> AND JUDA HIRSCH QUASTEL.

*From the Biochemical Laboratory, Cardiff City Mental Hospital.*

*(Received July 11th, 1935.)*

THE methods described in Part I of this series [Jowett and Quastel, 1935, 1], together with others described here, have been used to study the oxidation of the normal saturated fatty acids, containing from two to ten carbon atoms, by slices of rat and guinea-pig liver. The work has special reference to the formation of "ketone bodies" as products of oxidation and provides new and quantitative findings.

The results form a contribution to the problem of the mechanism of oxidation of fatty acids. It has been possible to estimate the approximate yields of ketone bodies from some of the fatty acids, which prove to be much higher than those hitherto obtained. The production of ketone bodies is definitely established as a major process in the oxidation; lack of evidence had hitherto led such authorities as Leathes and Raper [1925] to a sceptical view of their importance.

It has also been found that the simple  $\beta$ -oxidation theory of Knoop as applied by Embden to the breakdown of fatty acids in the liver, is unable to account for the facts observed. It will be remembered that according to the view of Embden and Marx [1908] decanoic acid is broken down successively to octanoic, hexanoic and butyric acids before acetoacetic acid is formed.

### EXPERIMENTAL METHODS.

Details of most of the methods used will be found in Part I. Briefly, liver slices have been shaken for two hours at 37° in various media in manometric vessels of the Warburg type. After the tissue slices have been removed to be dried and weighed, the residual solutions are employed for estimation of acetoacetic acid, or for the gravimetric estimation of ketone bodies, described later.

Estimations of acid-base changes have been made in a manner generally similar to that of Negelein [1925]. In these experiments lead perchlorate solution of density about 2.09, prepared according to Krebs [1930], has been used as manometer fluid in order to measure greater outputs of carbon dioxide than can be measured with Brodie's fluid. Lead perchlorate has also been used in a number of other experiments, and it has been found that it leads to an accuracy no less than with Brodie's fluid, since although the manometer changes are halved the readings are steadier.

In estimating the changes in fixed acid, account must be taken of the fact that when the solutions are acidified to decompose bicarbonate the acetoacetic acid present will be partially decomposed. The CO<sub>2</sub> evolution ascribed to bicarbonate will be slightly increased by this decomposition and the subsequent

<sup>1</sup> Beit Memorial Research Fellow.

CO<sub>2</sub> output in presence of aniline, ascribed to acetoacetic acid, will be lowered. A correction has been calculated on the basis of our measurement of the rate of decomposition of acetoacetic acid in solutions of  $p_H$  below 2 (Part I). A correction of 7.5% is added to the "observed" values for acetoacetic acid, when the solution has been maintained at the low  $p_H$  for 15 min. at 37° (for 20 min., 10% is added). A correction of the same absolute (not relative) amount is added algebraically to the value derived for production of fixed acid. The corrections do not essentially alter the values. The amount of acid added, usually about 0.15–0.2 ml. of *N* H<sub>2</sub>SO<sub>4</sub>, has always been sufficient to bring the  $p_H$  below 2 ( $c_H$  approximately 0.03), allowance being made for the amount of bicarbonate to be decomposed and for the buffering action of salts of weak acids present. The evolution of CO<sub>2</sub> is complete in 10–15 min. After reading the pressure changes the tissue slices are removed, and if acetoacetic acid is to be estimated the solution is brought at once to a  $p_H$  near 4.5 by addition of sodium acetate solution, the amount required being usually determined by calculation.

*Gravimetric estimation of ketone bodies.* The method of Van Slyke [1917] and of Peters and Van Slyke [1932] for blood has been adapted to a micro-scale. All details of the method of precipitation of the mercury compounds have been retained, such as times of refluxing and concentrations of reagents, but the size of apparatus has been reduced, and the volumes of solutions reduced from 175 ml. to 35 or 22 ml. The precipitates are washed on the centrifuge and transferred by suction to Jena sintered glass filters of type G4, which are weighed on a micro-balance.

In the accompanying table are summarised the results of control estimations. Sodium acetoacetate, freshly freed from acetone, has been standardised by the manometric technique of Part I, and the specimen of sodium  $\beta$ -hydroxybutyrate

used, when dried at 100°, has been taken as pure. For acetoacetic acid the factor tends to be lower for small quantities than Van Slyke's factor of 20, and an empirical correction has been applied for the deviations, although the use of data based on precipitates weighing less than 5 mg. has been almost completely avoided. For  $\beta$ -hydroxybutyric acid the factor 9.85 has been found and employed, which compares with Van Slyke's factor 8.45, and probably indicates a more complete oxidation to acetone than was found by Van Slyke.

Estimations show that in our experiments the quantities of acetoacetic acid and  $\beta$ -hydroxybutyric acid formed from fatty acids are usually of the same order, and to calculate "total ketones" we have therefore assumed that the amounts formed are equal.

The data and assumptions above lead to the following factors by which the weights of precipitates (mg.) are divided in order to convert weights of precipitate into  $\mu$ l. of gas at N.T.P.: acetone + acetoacetic acid 0.052;  $\beta$ -hydroxybutyric acid 0.046, total ketones 0.049.

In our experiments, summarised later, in which ketone bodies are estimated by this method, the contents of the manometer vessel, after removal of the tissue slices, are made up to known volume (usually 10–18 ml.) with water and 1/10 volume of the acid mercuric sulphate reagent of Van Slyke. After filtration through paper, a known volume of filtrate is at once taken for the estimation. Where manometric estimations are also made, these are effected on the contents of another manometer vessel which has undergone simultaneous shaking in the bath with similar solutions and a roughly equal quantity of liver slices.

*Manometric method for acetoacetic acid.* In applying the manometric method for acetoacetic acid, described in Part I, to the determination of a product derived from higher fatty acids, account must be taken of the possibility that the higher fatty acids may yield homologues of acetoacetic acid, which will probably react with aniline in a similar manner to acetoacetic acid.

Dakin [1923] has shown by liver perfusion experiments that hexanoic acid does not give rise to butyrylacetic acid, but only to acetoacetic acid. He compared the quantities of ketone bodies obtained after distilling the products of oxidation, (a) by the iodine titration method, which estimates propyl methyl ketone as well as acetone, and (b) by the gravimetric mercuric sulphate method, which estimates only acetone, as was shown by Dakin himself. The question raised is therefore answered for hexanoic acid.

We have found that in our experiments the products obtained react with aniline at the same rate as does acetoacetic acid within the experimental error of 5%. This statement applies to the products of oxidation of hexanoic, octanoic and decanoic acids, and to the product given by rat liver without added fatty acids. In a slightly less quantitative way the same statement may be made with respect to the other fatty acids used, which give small outputs of gas. Now it is probable that higher homologues of acetoacetic acid would react with aniline at rates different from that of acetoacetic acid. This result therefore provides some evidence that acetoacetic acid is the chief  $\beta$ -keto-acid produced in the oxidation of the fatty acids.

Much stronger evidence is derived from a direct comparison of (a) the acetoacetic acid as determined by the manometric method, and (b) the acetoacetic acid + acetone as determined by the gravimetric methods. Figures of this kind are given later and provide convincing evidence that acetoacetic acid is the only  $\beta$ -keto-acid produced in significant amounts from the fatty acids.

#### ACETOACETIC ACID PRODUCTION AND RESPIRATION OF GUINEA-PIG LIVER IN PRESENCE OF FATTY ACIDS.

In Table I are summarised illustrative experiments which show the rates of respiration and acetoacetic acid formation by guinea-pig liver in presence of the normal straight-chain fatty acids containing from two to ten carbon atoms. Every acid raises the respiration, and most of them increase the acetoacetic acid production. Usually there is an optimum concentration for acetoacetic acid production.

Table I. *Acetoacetic acid production and respiration in presence of fatty acids.*

\* At this concentration the solubility limit of calcium decanoate in the medium is reached.

Table II summarises the data obtained for the rate of acetoacetic acid production at concentrations of each fatty acid near the optimum. The acids with 4, 6, 8 and 10 carbon atoms produce acetoacetic acid the most rapidly, the 8- and 10-carbon acids being less active than the others. Acetic acid also produces acetoacetic acid, the rate being low but definitely above the very low rate found in its absence. Propionic acid does not produce any acetoacetic acid. Thus far the results are in accord with the findings of Embden and Marx [1908] on dog liver by the perfusion method, and of other workers.

A new result is seen on turning to valeric, heptanoic and nonanoic acids. These acids definitely produce acetoacetic acid, although at rates very much smaller than those characteristic of the neighbouring even-numbered acids. It was considered possible that, although acids of good quality were employed, the preparations of the odd-numbered acids might contain small amounts of the even-numbered acids, which might be responsible for the acetoacetic acid formation. We therefore compared, in one experiment, the rates of acetoacetic acid production using specimens of heptanoic acid obtained from three different sources (an old Kahlbaum specimen; a fresh B.D.H. specimen, and a fresh specimen from Cohen (Berlin), this last being freshly redistilled before use). All three specimens, used at a concentration 0.007 *M*, gave the same values of  $Q_{Ac}$  within the experimental error, the values observed being 1.36, 1.32 and 1.30, whilst the values for the respiration were all very similar. It is very improbable that values of this magnitude could be due to impurities, and that impurities of presumably varying amounts would bring about an equal rate. We therefore conclude that

acetoacetic acid production from fatty acids with odd numbers of carbon atoms is a real phenomenon, which must be taken into account in any theory dealing with the mechanism of oxidation of fatty acids.

No experiments have been made with acids containing more than 10 carbon atoms. With decanoic acid the low solubility of the calcium salt and the lowered rate of acetoacetic acid production were already beginning to make quantitative work difficult, and these difficulties will presumably be greater, though not insurmountable, with the higher acids.

*The relation between respiration and acetoacetic acid production.*

The data obtained show that there is a real relation between the increase in acetoacetic acid production and the increase in respiration brought about by fatty acids. Table III shows that, at approximately the optimum concentrations

for acetoacetic acid production, there tends to be a characteristic ratio for each fatty acid. The value of the ratio falls off as the concentration of the fatty acid rises, as can be calculated from many of the data given in Tables I and IV.

This is connected with the fact that whilst acetoacetic acid production passes through a maximum at a certain fatty acid concentration, when the acid has from 5 to 10 carbon atoms, the respiration continues to rise as the concentration is further increased. This in turn may, however, pass through a maximum at a higher fatty acid concentration (Table I, see also Quastel and Wheatley [1933]). The maximum concentrations tend to decrease as we ascend the series of fatty acids.

Table IV. *Inhibitory effect of higher concentrations of fatty acids on acetoacetic acid formation.*

		$Q_{Ac}$	0.31	1.45	1.20	0.82

\* In these concentrations calcium decanoate is precipitated in the medium. There is a rapid decrease of the respiration with time in the strongest concentration.

The ratios given in Table III show very clearly the great difference in behaviour between the acids with even numbers of carbon atoms and those with odd numbers. The difference is mainly due to the difference in acetoacetic acid production, but is exaggerated a little by the interesting fact (Table III) that the odd-numbered acids raise the respiration of liver more than do their even-numbered neighbours. This fact suggests that odd-numbered acids are oxidised more completely in the liver than are even-numbered acids.

It is seen in Table IV that raising the concentration of hexanoic acid well above its optimum value depresses the acetoacetic acid formation definitely, but that the inhibition is only partial. A similar effect was observed earlier with crotonic acid. The phenomenon, which is probably fairly general, is presumably an inhibition of a secondary type due to the high adsorption of the fatty acid anions. With decanoate, the inhibitory effect of higher concentrations may be due in part to the precipitation of calcium ion.

#### ACETOACETIC ACID PRODUCTION AND RESPIRATION OF RAT LIVER IN PRESENCE OF FATTY ACIDS.

The behaviour of rat liver is very similar to that of guinea-pig liver with respect to acetoacetic acid production, but there are a number of differences. Rat liver produces acetoacetic acid faster than does guinea-pig liver from the even-numbered acids (Table V). Butyric, hexanoic and octanoic acids yield acetoacetic acid at very similar rates, whilst the rate with decanoic acid is rather lower.

Rat liver without any added fatty acid yields acetoacetic acid at a definitely measurable rate, several times higher than that with guinea-pig liver. This phenomenon complicates the decision as to whether the other added acids can yield acetoacetic acid. In the case of acetic acid it is clear that acetoacetic acid is produced, and at a rate higher than with guinea-pig liver. Valeric, heptanoic and nonanoic acids do not however affect definitely the nett rate of acetoacetic

Table V. *Mean rates of acetoacetic acid production.*

acid production at the one set of concentrations at which they have been examined (Table VI).

That the odd-numbered acids are oxidised by rat liver is clear from the fact that they increase the respiration. The fatty acids generally do not however raise the respiration of rat liver as much as they do that of guinea-pig liver (Table VII), although they cause greater acetoacetic acid production. A possible explanation is that with rat liver there may be greater competition between the added fatty acids and the substrates already present. However this may be, the fact finds its expression (Table VII) in higher values for the ratio extra acetoacetic acid production/extra respiration for the even-numbered acids.

the acid showing the lower rate of production. A similar result was previously obtained for crotonic and butyric acids. Competition of this kind is probably a general phenomenon, indicating some common mode of oxidation for the different fatty acids.

Acetic acid however proves to be an exception (Table VIII), for  $Q_{Ac}$  in presence of butyrate and acetate is higher than when the acids are present alone. It would be expected that the mechanism of formation of acetoacetic acid from acetic acid would be of quite a different type from that involved in the oxidation of other fatty acids, and this result therefore accords with expectation.

*The formation of  $\beta$ -hydroxybutyric acid and acetone.*

It may appear to have been tacitly assumed in previous discussions, particularly in Part I, that acetoacetic acid is the only product of fatty acid oxidation which concerns us. This of course is not true, for acetoacetic acid is transformed in the liver in two ways.

One possible mode of breakdown of acetoacetic acid in liver is to acetone and carbon dioxide. Some evidence that acetone as well as acetoacetic acid resulted from fatty acid oxidation in the perfused dog liver was obtained by Embden and Engel [1908], but the decomposition may have been due to the perfusing blood, since according to Grégoire [1933] dog blood decomposes acetoacetic acid to acetone. A few figures we have obtained (Table IX) suggest that some acetone is formed during oxidation of fatty acids by rat liver. The rate of formation of acetoacetic acid + acetone, estimated gravimetrically, is greater than the rate of acetoacetic acid formation estimated manometrically, and probably therefore acetone is being formed from acetoacetic acid. A more definite and interesting conclusion to be drawn from the figures is that acetoacetic acid is the only  $\beta$ -keto-acid formed to an appreciable extent in the experiments. If a higher homologue of acetoacetic acid were formed it would probably be estimated by the manometric method but not, in view of Dakin's experiments already mentioned, by the gravimetric method.

Acetoacetic acid is also transformed in another manner in liver, namely to  $\beta$ -hydroxybutyric acid. We have already shown that in the oxidation of butyric and crotonic acids by guinea-pig liver  $\beta$ -hydroxybutyric acid is not an intermediary product in the formation of acetoacetic acid. In these cases therefore the formation of  $\beta$ -hydroxybutyric acid results from a reduction of acetoacetic acid, and it is likely that the same is true for other fatty acids. The figures given in Table IX show that quantitatively  $\beta$ -hydroxybutyric acid is an important product of fatty acid oxidation in the liver, the amount formed in most of our experiments being of the same order as that of acetoacetic acid. Formation of  $\beta$ -hydroxybutyric acid by the liver has been shown to take place from butyric acid [Friedmann and Maase, 1910, and others] and from hexanoic acid [Dakin,

Table IX. *Gravimetric estimations of ketone body formation.*

The symbol  $Q_{Ac}$ , hitherto used to indicate rate of acetoacetic acid production by the manometric method, is also used to indicate rate of formation of acetoacetic acid + acetone, by the gravimetric method, and is then always distinguished by the statement that the gravimetric method was used.

$Q_{ox}$  indicates similarly the rate of formation of  $\beta$ -hydroxybutyric acid, and  $Q_{ket}$  the rate of formation of total ketones, both estimated gravimetrically.

1923], but as far as we are aware it has not previously been shown to take place from other normal saturated fatty acids.

A very rough estimate of the average ratios of the substances making up the total ketone bodies produced from fatty acids by rat liver in our experiments is acetoacetic acid 0.5, acetone 0.1,  $\beta$ -hydroxybutyric acid 0.4. The proportions will not necessarily be the same for other experimental conditions. The breakdown of

acetoacetic acid to acetone is almost certainly irreversible, and the proportion of acetone will therefore increase with time. The ratio of acetoacetic acid to  $\beta$ -hydroxybutyric acid varies in our experiments, and the nett rate of transformation of one of these substances into the other will presumably depend on the supply of other metabolites to the liver cells. The cells will tend to set up a dynamic equilibrium between these two substances, the position of the equilibrium being dependent on the conditions.

Accepting, as we do, the view that acetone and  $\beta$ -hydroxybutyric acid are products derived from acetoacetic acid, it is important for us to know whether the nett acetoacetic acid formation in any one liver bears a constant ratio to the formation of total ketone bodies, for on this view the total ketone bodies measure the gross acetoacetic acid formation. It is, for instance, desirable for us to know whether a substance that inhibits the nett acetoacetic acid production to a certain extent inhibits also the gross acetoacetic acid production to an equal extent.

We cannot claim that this is always the case, but where the point has been tested by us it is true. An experiment recorded in Table IX shows that benzoate inhibits the nett formation of acetoacetic acid from butyric acid by guinea-pig liver to the same extent as it inhibits total ketone formation. Similar evidence of a more qualitative kind regarding the inhibiting action of benzoate is presented later.

If  $\beta$ -hydroxybutyric acid is derived from acetoacetic acid, and not from butyric acid more directly, it would be expected that acetoacetic acid might yield  $\beta$ -hydroxybutyric acid at a rate faster than butyric acid does. This expectation has been verified by an experiment with guinea-pig liver (Table IX), which therefore supports the views put forward.

#### *The yield of ketone bodies from fatty acids.*

In the experiments recorded in other sections of this work we have endeavoured to maintain the fatty acid concentrations at levels which do not fall very much with time, so that the rates of oxidation are measured under fairly definite conditions.

In this section, on the other hand, we present experiments in which the object has been to allow the tissue to remove the fatty acid completely during the experiment, the period of which has however been restricted as before to two hours. The fatty acid concentrations have been lowered and the quantity of tissue increased. Several manometer vessels have been set up in each experiment. In each vessel the volume of solution and the initial concentration of the fatty acid have been the same, but the weight of tissue has been varied. By comparing the quantities of ketone bodies formed in the presence of varying weights of tissue, it should be possible to tell whether any of the quantities of tissue has been sufficient to transform the fatty acid completely, for when this object is attained the quantity of ketone bodies formed will be expected to become constant. We appear to have been successful in this object, but two difficulties arise in the exact interpretation of the experiments.

(1) In the absence of added fatty acids, liver gives rise to some acetoacetic acid. Increasing the quantity of tissue indefinitely will therefore probably increase the quantity of ketone bodies indefinitely. We can to some extent meet the difficulty (a) by choosing a liver with relatively low "spontaneous" acetoacetic acid production, i.e. guinea-pig liver rather than rat liver, and (b) by attempting to correct for the "spontaneous" acetoacetic acid formation.

(2) A second source of error, which however is small in our experiments, is the necessity of correcting for the quantity of ketone bodies removed from the vessels with the tissue slices. We find that the loss in weight of the vessels when the tissue slices are removed is for guinea-pig liver about six times the dry weight of the slices found subsequently. We have calculated the correction to be applied on the basis that the ketone bodies removed are equal to the quantity contained in an equal quantity of solution. As there may not be equal partition of ketone bodies between liver slices and medium, the assumption may lead to an error of a few per cent. in our results<sup>1</sup>.

Details of one of our experiments are recorded in Table X, which make clear the nature and magnitude of the corrections applied. The results of the experiments are shown in Table XI, where the several values obtained in each experiment, both corrected and not corrected for the "spontaneous" acetoacetic acid formation, are shown.

Table X. *Experiment showing yield of acetoacetic acid from hexanoic acid.*

O<sub>2</sub>. 3.2 ml. of solution containing glycerophosphate buffer. Guinea-pig liver.

Vessel	1	2	3	4
Initial conc. hexanoate (M)	—	0.0025	0.0025	0.0025
After 117 min. shaking at 37°, tissue removed from vessels, to which were added 0.2 ml. aniline hydrochloride and 0.3 ml. N acetic acid. <i>r<sub>F</sub></i> = 3.7.

† Acetoacetic (corrected) Hexanoic	—	0.86	0.81	0.55
<i>Q</i> <sub>O<sub>2</sub></sub> (14-117 min.)	4.59	7.82	7.80	8.13
<i>Q</i> <sub>A</sub> (0-117 min.)	0.26	1.91	2.14	2.61

In Table XI are also shown the results of a similar series of experiments carried out in the presence of 0.04M sodium malonate. Malonate raises the spontaneous acetoacetic acid formation in guinea-pig liver [Jowett and Quastel, 1935, 2] and it was thought that by increasing the correction for this it would be made clear whether or not this correction should be applied. It was found later, however, that malonate inhibits the breakdown of acetoacetic acid by liver, and the complete interpretation of the experiments is, therefore, difficult.

The first set of experiments may be taken to show that butyric acid yields about 0.3-0.5 mols. of acetoacetic acid, hexanoic about 0.9, octanoic 0.6, and decanoic acid 0.6.

The highest yields of acetoacetic acid previously obtained from these fatty acids were derived from the experiments of Embden and Marx [1908] with dog

<sup>1</sup> It may be pointed out that the correction discussed has not usually been applied to experiments in other sections of this work. For 20 mg. of guinea-pig liver in 3.2 ml. solution, the correction amounts only to 4%, and for relative results in any one experiment is much less.

Table XI. *Yields of ketone bodies from fatty acids.*

livers. These figures show a yield of 0.12–0.18 mols. of acetone + acetoacetic acid per mol. of fatty acid, uncorrected for the “spontaneous” production by the liver. It was not proved or even suggested in these experiments that the fatty acids added were completely removed by the liver. The low values of the figures have however made Leathes and Raper [1925] sceptical of the importance of ketone bodies in fatty acid metabolism, and it is only evident now that acetoacetic acid is a quantitatively important product of fatty acid oxidation.

An even more interesting figure than the yield of acetoacetic acid is the yield of total ketones from the fatty acids. A few experiments have been made to determine total ketone yields on similar lines to those carried out with acetoacetic acid, and they are summarised in Table XI. The medium in these experiments was Ringer's solution (5%  $\text{CO}_2$ , 0.025 *M*  $\text{NaHCO}_3$ ). In the “blank” vessels, *i.e.* those to which no fatty acid was added, the quantity of total ketones found as mercury precipitate did not exceed 0.44 mg., which corresponds to a value of  $Q_{\text{ket}}$  of 0.09.

The Van Slyke method is probably inaccurate for the small precipitates in question, and we have assumed a “blank” value  $Q_{\text{ket}} = 0.2$  for the purpose of calculating “corrected” values for the yield of total ketones. The experiments give us values of 1.15–1.3 mols. of total ketones from hexanoic acid, 1.1–1.3 from octanoic acid, and 0.7–0.85 from decanoic acid. The value found with butyric acid, 0.2–0.35, is probably rather too low, in view of the higher yield of acetoacetic acid previously found.

We cannot state with certainty that any of the values definitely exceeds one molecule of total ketones per molecule of fatty acid, and the results may be

summarised as follows: hexanoic and octanoic acids each yield about one molecule of ketone bodies, decanoic acid slightly less and butyric acid  $\frac{1}{2}$ – $\frac{1}{3}$  molecule.

The yield of ketone bodies from butyric acid is much less than that from the higher acids, and it is therefore very unlikely that the higher acids yield ketone bodies exclusively by a mechanism by which they first break down to butyric acid.

It is possible that a proportion of the fatty acid is broken down by a path that does not lead to ketone body formation, and the greater yields of ketone bodies which have been found with fatty acids higher than butyric acid may be explained on the following lines: (a) acetic acid may be one of the products of breakdown of higher fatty acids, and this may be an additional source of acetoacetic acid, or (b) octanoic and decanoic acids may break down into two units containing four carbon atoms and thereby yield two molecules of acetoacetic acid<sup>1</sup>.

It is unlikely, however, that the production of acetic acid from hexanoic acid will explain the very considerable difference between the yields of acetoacetic acid from this acid and from butyric acid, for this would necessitate the complete conversion of acetic acid into acetoacetic acid.

This section may be concluded by giving some values (Table XII) for the acetoacetic acid formed per molecule of fatty acid added, which were obtained in experiments not specially designed for obtaining complete removal of the fatty acid. The figures given are therefore lower than the actual yields that could be obtained, but may serve for the present to indicate minimum values of the yield of acetoacetic acid, for some cases where a better approximation is not yet available. The figures are sufficient to show that guinea-pig liver produces acetoacetic acid from heptanoic and nonanoic acids to a small but definite extent. It is also clear that rat liver produces acetoacetic acid from the even-numbered fatty acids to a considerable extent.

Table XII. *Yields of acetoacetic acid.*

*Acid-base changes during fatty acid oxidation.*

A series of experiments is summarised in Table XIII in which the change in the bicarbonate concentration of the Ringer's solution employed as medium is used to measure the production or disappearance of fixed acid during the oxidation of fatty acids by guinea-pig liver. The symbol  $Q_s$ , defined on similar lines to the others employed, denotes acid production. As is usual, no attempt has

<sup>1</sup> The probability of this latter mode of breakdown is enhanced by the conclusion drawn, in work recently published by Butts *et al.* [1935], that the intact rat can break down octanoic acid to two molecules of ketone bodies. These authors consider that in the rat butyric and hexanoic acids yield about one molecule of ketone bodies.

Table XIII. *Acid production during fatty acid oxidation.*

\* See footnote to Table IX.

been made to correct values of  $Q_s$  for the buffering power of the tissue slices, or for the very slight buffering due to the bicarbonate-carbonate system, and the results will all be numerically a little too low.

The results are illuminating, although not very numerous. It may first be noted that there is evidence of a definite parallelism between  $Q_s$  and  $Q_{Ac}$  in the cases where several experiments have been done with any one acid. The parallelism provides some evidence that the acid-base changes are directly connected with fatty acid oxidation and are not due to a secondary stimulation or inhibition of other processes in the liver.

Hexanoic, octanoic and decanoic acids all show acid production definitely exceeding the small acid production by liver in the absence of added fatty acid. Butyric acid on the other hand shows a slight disappearance of acid as compared with the control.

The reactions

which occur with butyrate lead to no acid-base change, while the reaction

which probably occurs to a small extent, leads to disappearance of fixed acid. It may be concluded that any other type of oxidation which butyrate may undergo does not lead to much nett appearance or disappearance of acid groups.

The reactions occurring with the higher even-numbered acids may on two views at least be expected to lead to production of acid.

(1) The reaction with hexanoic acid may be

and on the same lines the higher acids would give two or more molecules of acetic acid. It must be made clear that there is no evidence whatever, of which

we are aware, that acetic acid is a product of fatty acid oxidation. That any acid at all is produced during the oxidation of fatty acids by liver, beyond acetoacetic and  $\beta$ -hydroxybutyric acids, is a fact which has not been shown prior to the present work.

The hypothesis that acetic acid is formed is not easy to test from our data. Reactions such as the one formulated lead to quite definite ratios between the acid production that should be observed and the formation of acetoacetic acid +  $\beta$ -hydroxybutyric acid. With hexanoic acid the ratio  $Q_n/Q_{ket}$  should be 1, with octanoic 2, with decanoic 3. The position is complicated by the fact that part of the acetic acid hypothetically formed would react further, and in such a way as to lower the expected ratios below the values given.

Acetic acid itself forms acetoacetic acid, and furthermore, if the process is a condensation,

fixed acid will disappear. Disappearance of fixed acid is observed, in fact, with acetic acid in liver, but its amount is probably greater than can be accounted for by the rate of acetoacetic acid formation, and it may be that some of the acetic acid is oxidised completely, with disappearance of fixed acid.

In spite of the complications, it would be expected on the hypothesis that the ratio  $Q_n/Q_{ket}$  would rise as we pass from hexanoic to octanoic and from octanoic to decanoic acid. The observed ratios (0.5, 0.7, 0.7), however, do not lead to a definite conclusion. Attempts to isolate acetic acid as a product of fatty acid oxidation should settle the question. A few experiments we have made in this direction have as yet given no definite results.

(2) It has been found by Verkade and van der Lee [1934, 1] that when human subjects are fed on glycerides made from pure saturated fatty acids, the reaction

takes place in the body to some extent when  $n+2$  has values of 8 to 12, for small quantities of the dibasic acid are excreted in the urine. Such a process as that formulated would lead to the observation of fixed acid production in our experiments. It is, however, unknown whether the production of dibasic acids takes place in the liver or elsewhere in the body. The yields of dibasic acid in the urine are also small in relation to the quantity of fatty acid ingested—octanoic acid giving up to 0.18% and decanoic acid up to 2.2% of the yield theoretically possible—and it is therefore unknown whether a considerable proportion of the fatty acid is oxidised in this way in the human body. From our results on the total ketone production from hexanoic acid, we conclude that hexanoic acid at least does not undergo oxidation in guinea-pig liver to dibasic acid as a final product to any appreciable extent, hence it is unlikely that the acid production observed in this case can be due to the formation of dibasic acids.

The reaction formulated, however, together perhaps with degradation to lower dibasic acids [Verkade and van der Lee, 1934, 2], cannot at present be excluded as a possible partial path of oxidation for a number of the fatty acids.

Let us now consider the problem of the oxidation of the odd-numbered acids. It will be seen that when propionic acid is oxidised, there is a considerable disappearance of fixed acid. This may be due to complete oxidation of some of the propionic acid, and perhaps, as already suggested [Dakin, 1922], lactic and pyruvic acids are intermediaries in the oxidation.

With valeric acid fixed acid also disappears, whilst with heptanoic acid there is apparently slight acid production. With both these acids formation of acetoacetic acid is higher than would be expected if acetic acid is the inter-

mediary that gives rise to it. It is probable that valeric acid gives rise directly to some acetoacetic acid but the disappearance of fixed acid suggests that a more important mode of oxidation may be through propionic and acetic acids or their partially oxidised derivatives. The reaction may be primarily:

the propionic acid undergoing complete oxidation, the nett result being a disappearance of fixed acid but rather less than in the case of propionic acid alone owing to the presence of the hypothetical acetic acid.

When heptanoic acid is oxidised we imagine the same process extended, so that a molecule of propionic acid and two molecules of acetic acid are formed. The nett result of this process would be greater fixed acid production than in the case of valeric acid. Acetoacetic acid production from heptanoic acid cannot be explained as dependent upon the formation of acetic acid.
